THE ELECTRICIAN:

A WEEKLY JOURNAL OF

THEORETICAL AND APPLIED ELECTRICITY AND CHEMICAL PHYSICS.

VOLUME X.

FROM NOVEMBER 18, 1882, TO MAY 12, 1883.

LONDON:

Printed and Published by JAMES GRAY, at the Office, 396, Strand, in the City and Liberty of Westminster.

1883.

INDEX TO VOL. X.

-14531-

A

Abel, Prof. F.A., Electricity Applied to Explosive Purposes, 561.
Accumulators (*see* BATTERIES, SECONDARY).
Akester's Arc Lamp, 380.
Altenech-Siemens Armature, Winding of, 256.
Amalgamation for the Supply of Electricity, 588.
Annual Meetings, 132.
Aquarium, Westminster, Exhibition at (*see* EXHIBITIONS).
Arc Lamps :—
  Akester's, 380.
  Gray's, 513.
  Lea's, 491.
  Staite's, 158.
Arc, Spectroscopic Experiments with, Profs. Liveing and Dewar, 419.
Armington and Sims's Engine, 440.
Atkinson, Ll.B., Transmission of Power, 89, 117.
Aurora, Displays of, 43.
Aurora (*see* also EARTH CURRENTS).
Ayrton, W. E., Electric Lighting and Locomotion, 355, 403, 429, 450.
Ayrton and Perry's Dynamo, 403.
Ayrton and Perry's Motors, 404.

B

Balances, Electric, Thompson's and Deprez's, 211, 212.
Ball's Unipolar Dynamo, 465.
Barker, G. F., Secondary Batteries, 501, 524.
Batteries, Primary :—
  Bichromate of Potash in, J. T. Sprague, 376.
  Chardin's Portable Medical Battery, 536.
  Insulite, 614.
  Effects of Temperature on E.M.F., &c., of, W. H. Preece, 367.
Batteries, Secondary :—
  By G. F. Barker, 501, 524.
  Charging of, R. H. M. Bosanquet, 86.
  Chemistry of the Planté and Faure, Gladstone and Tribe, 570.
  By C. W. S. Crawley and E. C. Rimington, 57.
  Mr. Edison's Opinion of, 329, 396.
  Faure-Sellon-Volckmar, Trial at Kew, 430.
  By Prof. O. J. Lodge, 111, 225.
  Smith's High Pressure, 449.
  (*See also* CORRESPONDENCE and NOTES).
Bayley's Electric Light Switch, 515.
Becquerel, Madame, Death of, 473.
Bell, A. Graham, Detection of Metal in the Body, 138, 165, 191, 212.
Bennett's Insulators, 319.
Bennett's Telephonic Translators, 202.
Berechurch Hall, Electric Light at, 66.
Bichromate of Potash in Batteries, J. T. Sprague, 376.
Bidwell, Shelford :—
  Method of Measuring Resistances, 423.
  Microphonic Contacts, 547, 572.
  Resistance of Carbon Contacts, 296.
  Selenium Cells, 82.
Blackburn's Portable Testing Bridge, 488.
Blakesley, T. H., Report on Brush Company's Provisional Order for Canterbury, 607.
Blakesley, T. H., Superposition of Currents, 377.
Blyth, Prof. J., Measurement of Electric Currents, 589.
Blyth, Prof. J., Action of the Microphone, 42.
Books, Notices of (*see* REVIEWS).
Bosanquet, R. H. M., Charging Secondary Batteries, 86.
Bramwell, Sir F., on Telephones, 402.
Brewtnall's Suspension for Electroliers, 471.
British Association Unit, Lord Rayleigh, 297.
Brown W., Conservation of Energy, 11.
Brünn Theatre, Electric Light in, 38, 275.
Brush Dynamo, Description of, 271, 379.
Buchanan's Magnetic Separator, 496.

C

Cabanellas, G., on Deprez's Munich Experiments, 40.
Cable Testing, A Guide to Practice in, 13, 63, 106, 153, 199, 254, 317, 365, 414, 464, 487, 511, 534, 559, 584, 605.
Cable Work in 1882, 183, 229.
Cables, Report of International Conference for the Protection of, 16.
Canterbury, Report on Brush Company's Provisional Order, T. H. Blakesley, 607.
Cantor Lectures (*see* DYNAMOS), by Prof. S. P. Thompson.
Carbon Contacts and the Microphone, O. Heaviside, 293.
Carbon Contacts, Resistance of, S. Bidwell, 296.
Carbon, Influence of Gases on Conductivity of, A. W. Soward and I. Probert, 496.
Chardin's Portable Battery for Medical Purposes, 536.
Chelsea Vestry, Suggested Amendments in Draft Provisional Order, 250.
Chelsea Vestry, Report on Electric Lighting to, 112.
Chemical Corrosion, Electrolytic Balance of, G. Gore, 381.
Cherry, William, Death of, 563.
Chertemps-Dandeu Dynamo Machine, 115.
Circuits, by J. T. Sprague, 128, 247.
Circuits, by F. C. Webb, 31, 105, 127, 177, 203, 375, 393, 486.
City and Guilds of London Institute, Criticism of Annual Report of, 444.
City and Guilds Institute Exam. Papers, 15, 37, 61, 85, 161, 184, 249, 326, 350, 443, 515.
Civil Engineers, Institute of (*see* SOCIETIES).
Clark, Muirhead and Company's Work in 1882, 230.
Companies Formed in 1882, List of, 181.

COMPANIES' MEETINGS, REPORTS, &c. :—

(* Indicates Special Edition.)

  American Bell Telephone, 508.
  Anglo-American Brush, 50, 239, 259, 267, 287, 311.
  Anglo-American Telegraph, 287, 334.
  Birmingham and Warwickshire Brush, 46.
  Brazilian Submarine Telegraph, 576, 616.
  British Insulite, 309.
  Brush Midland Electric Light, 22.
  Brush Electric Light of Scotland, 71.
  Cuba Submarine Telegraph, 263, 285.
  Devon and Cornwall Electric Light, 24, 214.
  Direct Spanish Telegraph, 455, 503.
  Direct United States Cable, 310*, 332.
  Dublin Electric Light, 263.
  Eastbourne Electric Light, 480.
  Eastern Telegraph, 239, 257, 283.
  Eastern Extension Telegraph, 550.
  Electric Lighting, Contract, and Maintenance, 616.
  Electrical Power Storage, 454, 504.
  Electro-Amalgamator, 286.
  Faure Electric Accumulator, 95, 140.
  German Union Telegraph, 432, 455.
  Great Northern Telegraph, 530, 617.
  Hammond Electric Light, 618.
  India Rubber, Gutta Percha, and Telegraph Works, 312, 335.
  Indo-European Telegraph, 598.
  Lancashire Maxim-Weston Electric Light, 262.
  Maxim-Weston Electric, 362, 574, 619.
  Mediterranean Extension Telegraph, 93, 405.
  Montevidean and Brazilian Telegraph, 504.

COMPANIES' MEETINGS, &c. (*continued*) :
  Oriental Telephone, 19, 96, 258, 312, 332*.
  Provincial Brush, 460.
  Railway and Electric Appliances, 262.
  Reuter's Telegram, 576.
  South-Eastern Brush, 460.
  Submarine Telegraph, 358.
  Swan United, 121.
  Telegraph Construction and Maintenance, 312, 359, 382.
  The Telephone, 336.
  Western and Brazilian Telegraph, 192, 215, 258, 431, 480.
  Yorkshire Brush Electric Light, 23, 260.

COMPANIES, NEW :—
  American Electric Storage Co., 481.
  American Postal Telegraph Co., 505.
  Bernstein Electric Light Co., 433.
  Canadian Electric Light Co., 265.
  Edison Light Co. of Milwaukee, 433.
  Edison Electric Light Company of San Francisco, 97.
  Electric Fire Alarm and Signals Co., 49.
  Electric Supply Co. of San Francisco, 313
  Electrical Accumulator Co. of New York, 433.
  Faure Electric Storage Co. of New York, 73.
  Incandescent Electric Lighting Co., 73.
  Long Distance Telephone Co., 579.
  M'Tighe Electric Light, 553.
  Manhattan District Telegraph Co., 49.
  New York and Brooklyn Electric Light Co., 313.
  New York and Pennsylvania Telegraph and Telephone Co., 145.
  Olmstead Electric Light Co., 49.
  Overland Telephone Co. of New York, 433.
  Sperry Electric Light Motor, &c., Co., 361.
  Sun Light Co. of New York, 433.

Cooke, C. W., Report on Electric Lighting to Sheffield Corporation, 279, 304.

CORRESPONDENCE :—
  Accumulators (*see* BATTERIES, Secondary).
  Alloys, Resistance of, 249.
  Arc Lamp, to burn at any Angle, 374, 395, 425.
  Arc Lamps, Carbons in, 586.
  Aurora, The, and Edison's Lamp, 163.
  Ayrton and Perry's Erg-meter, 394, 424.
  Ayrton and Perry, Lamps for Carriages, 43.
  Bandsept, A., Electrical Machines and the Transmission of Power, 541.
  Banks, W., Telephone Switch Bell, 347.
  Batteries, Primary, Clarke's Portable, 446.
  Batteries, Secondary :—
    Charging of, 10.
    and Mr. Edison, 374, 395, 470.
    The Efficiency of, 446.
    The Faure-Sellon-Volckmar, 469.
    How can they be made, 279.
    Lines suggested by "W.'s" Letter on, 395, 470.
    at Mr. Reckenzaun's Lecture, 134, 163.
    for Telegraphy, 278.
    Where can they be had? 65, 83.
  Bennett, A. R., Telephonic Translators, 394.
  Berliner, E., Microphone Contacts, 135, 163.
  Berliner, E., Action of Microphone, 347.
  Bicycle, Dynamo wanted for, 59.
  Blakesley, T. H., Electrical Transmission of Energy, 10.
  Books on Electrical Subjects, 586.
  Bowman, R., Arc Lamp to Burn at any Angle, 425.
  Bowman, R., Portable Lamp, 445.
  Cable Testing, 231.
  Carbons in Arc Lamps, 586.
  Carbons, Platinising of, 445.

Digitized by Google

CORRESPONDENCE (*continued*):
Clark, Latimer, Wedgwood's Telegraph, 519.
Clark, Forde and Co. Safe Working Currents, 495, 519.
Clarke's Portable Battery and Gaslighter, 446.
Commissioners of Sewers and M. Heaphy, 587.
Commutators, Diagonal Slitting of, 424.
Conductors, Kirk's Method of Connecting, 519, 542.
Cowley, F., Storage Batteries, 65.
Crompton's Compound Machine, 134, 135, 162, 179, 186.
Currents, Behaviour of, 424.
Currents, Safe Working, 395, 425, 446, 495, 519.
Currents, Superposition of, 395.
Diddler, J., How it Can be Done, 542.
Diserens, J. H., Accumulators, 279.
Dynamo Machines:—
Compound, 134, 135, 162, 179, 232, 298, 351.
The Gramme Ring, 586.
Higgs's Improvement of, 424.
High Speed, 587.
Method of Obtaining Curve of E.M.F., 186.
And the Transmission of Power, 541, 566.
Unipolar, 494, 517, 518.
Earth Currents, 520.
Earthquakes and their Origin, 565.
Electric Lamps for Carriage, 11, 43.
Electric Light:—
By the Aurora, 163.
Companies and their *Employés*, 494.
Conductors, Kirk's Method of Connecting, 519, 542.
Engineers, Gauge for, 470.
Wires, Insulating, 566.
Electric Lighting of Nottingham, 611, 612, 613.
Electrical Power Storage Co., 469, 470.
Electrician "Supplement No. II.," Method of Calculation Employed, 425, 446.
Electricity, Storage of, 278.
Energy, Electrical Transmission of, 10.
Engine, Farcot's Compound, 446.
Erg-meter, Ayrton and Perry's, 394, 424.
Fahie, J. J., Cable Testing, 231.
Fahie, J. J., Resistance of Alloys, 249.
Fahie, J. J., Society of Telegraph Engineers, 445.
Fahie, J. J., Younger Days of Gas, 613.
Farcot Compound Engine, 446
Farquhar, W. T., Reis's Telephone, 494.
Faure-Sellon-Volckmar Accumulator, 469.
Fittings for Incandescent Lamps, 278.

Electrician Dinner, 1883, 517.
Electrician "Supplement, No. II." (*see* issue of March 3, 1883).
Electrician "Supplement, No. III." (*see* issue of April 28, 1883).
Electricity:—
Amalgamation for the Supply of, 588.
Cost of, 589.
Applied to Explosive Purposes, F. A. Abel, 561.
Elementary Principles of, 34, 64, 79, 125, 173, 197, 413, 462.
Hopkinson's Improvements in the Measurement and Distribution of, 479, 502.
Measurement of, J. N. Shoolbred, 372, 377.
Novel Uses for, 276.
Some Theorems in, O. Heaviside, 55.
Electroliers, Brewtnall's Suspension for, 471.
Electroliers, Verity's Cup and Ball Joint for, 536.
Electrolytic Balance of Chemical Corrosion, G. Gore, 381.
Electrometer, Thomson's Quadrant, 198.
Electro Pulveriser, The Manes, 591.
Electrostatic and Magnetic Relations, O. Heaviside, 510, 558, 582.
Elphinstone-Vincent Dynamo, 233, 471.
Energy, Conservation of, 11.
Engines:—
Armington and Sims, 440.
Davey Paxman and Co.'s, 131.
Examination Papers and Answers, 15, 37, 61, 85, 161, 184, 249, 326, 350, 443, 515.
Exhibitions:—
At Crystal Palace:—
Gas at, 300.
Lea's Arc Lamp, 491.
Sax's Water Gauge and other Exhibits, 490.
At Munich:—
Phosphor-Bronze Wire, 54.
Siemens' Electro Plating Dynamo, 54.
Swan and Maxim Lamps at, 54.
At Vienna, Regulations, 238.
At Westminster Aquarium:—
Lumley Dynamo at, 392
(*see also* NOTES).
Explosive Purposes, Electricity Applied to, F. A. Abel, 561.

American Bell Telephone Company, 508.
Anglo-American Brush Corporation, Circular issued by, 207.
Anglo-American Electric Light Company, 242.
Appointments:—
Major R. Y. Armstrong, Superintendent under Electric Lighting Act, 457.
A. R. Bennett, Engineer to National Telephone Company, 433.
Captain P. Cardew, Instructor in Telegraphy, Chatham, 457.
G. G. Cleather, Manager of Crystal Palace, 553.
T. R. Comyn, to Lancashire Maxim-Weston Company, 25.

Digitized by Google

NOTES (*continued*):
Appointments:—
T. R. Comyn, Secretary to Maxim-Weston Company, 457.
J. Donaldson, Postmaster at Trowbridge, 337.
J. Gregson, Postmaster at Workington, 337.
T. H. S. Hawker, as Electrician to Birmingham and Warwickshire Brush Company, 241.
W. Jackson, as Secretary to Eastern Electric Light Company, 169.
J. K. D. Mackenzie, to Metropolitan Brush Company, 25.
B. Murphy, Postmaster at the Curragh, 385.
F. R. Reeve, as Manager of Jablochkoff Company, 73.
Senor L. del Rey, Director-General of Spanish Telegraphs, 481.
J. Samuel, as Postmaster of Arundel, 241.
G. C. Steel, Chief Medical Officer at the General Post Office, 193.
R. Ward, as Chief Engineer of Metropolitan Brush Company, 217.
H. Watt, to Maxim-Weston Company, 1.
Arc Lamps, New, Akester's, 26.
Arc, Voltaic, between Platinum Electrodes, 2.
Arc, Voltaic, Resistance of, 580.
Armatures, Bursting of, 579.
Armington Engine, an Extraordinary Run, 506.

THE ELECTRICIAN:

A WEEKLY JOURNAL OF

THEORETICAL AND APPLIED ELECTRICITY AND CHEMICAL PHYSICS.

No. 1.—Vol. X. SATURDAY, NOVEMBER 18, 1882. Price 4d.

SLIP

Brazilian Submarine Telegraph Company.—The traffic receipts of this company for the week ended November 10 were £3,626.

Electric Light for War Purposes.—Two electric lights have been erected at the entrance of the Gulf of Spezzia in Italy to illuminate it in time of war.

The Telephone in Mexico.—It is stated that before long a telephone line will unite Vera Cruz and Mexico. The distance between these towns is 372 kilometers.

Alderney.—The cable between Guernsey and Alderney is interrupted. All telegrams, therefore, for the last-named place have to be forwarded by post from Guernsey.

Eastern Extension Telegraph Company.—The traffic receipts of this company for the month of October, 1882, amounted to £29,925, and to £31,164 for the corresponding period of 1881.

Direct Spanish Telegraph Company.—The estimated traffic receipts of this company for the month of October, 1882, amounted to £2,079, against £2,063 in the corresponding period of last year.

Notice.—Owing to the pressure on our space we are compelled to leave over our report on the Munich Exhibition, an article by M. Cabanellas on M. Deprez's experiments at Munich, and other matter.

The Royal Society.—At the anniversary meeting of this society, on the 30th instant, Mr. William Spottiswoode will be proposed for election as president again, and Professor W. Grylls Adams as a member of council.

The Telephone in Nottingham.—The number of messages transmitted through the National Telephone Company's Exchange at Nottingham for the week ending November 2, 1882, was 4,900, being 700 increase on the previous week.

Crystal Palace Exhibition.—The amount subscribed by the various gas companies towards the expenses of the special committee of the gas institute appointed to organise the gas exhibits at this exhibition now reaches £5,458 12s.

Electric Light in Cleveland.—The Ohio Electric Light and Power Company of Cleveland, U.S.A., which employs the Sherman lamp, is proposing to light certain streets by erecting arches of gas pipe from kerb to kerb, from which the lamp is suspended.

Western and Brazilian Telegraph Company.—The traffic receipts of this company for the week ending 10th November, 1882, were £2,327, after deducting the "fifth" of the gross receipts payable to the London Platino-Brazilian Telegraph Company.

Edison Lamps on Board Ship.—Two steamers of the Union line are to be fitted with Edison lamps. The motors in these instances will be Brotherhood three-cylinder engines. Lengthened trials are being carried out with these engines as motors for Edison machines.

Electric Light for Ripon (Yorks.).—The town council of Ripon have resolved to oppose the applications of companies for leave to supply electricity, and have also decided not to apply for a provisional order to supply it themselves. The gasworks are owned by the town council.

The Lighting of the Royal Palaces.—We hear that the work connected with the lighting of Windsor Castle and the Royal palaces has been placed in the hands of Mr. W. H. Massey, of Twyford, Berks, who some time ago resigned the post of general manager of the Maxim-Weston Company.

Great Northern Telegraph Company.—The traffic receipts of this company for October, 1882, amounted to £21,440; for the period from 1st January to 31st October, 1882, they were £203,280, for the corresponding months of 1881 £201,359, and for the same period of 1880 £198,991.

The Bell Telephone Patent.—An American paper says:—"The Bell patent would, it is considered by those competent to form an opinion, be cheap at 10,000,000 dols. The consolidated telephone interests of the United States are estimated at from 100,000,000 dols. to 150,000,000 dols."

New Atlantic Cable.—The *New York Herald* of recent date announces the arrival of Mr. Bennett in that city with the special object of completing arrangements with Mr. Garrett, of the Baltimore and Ohio Railroad, for laying the new cable. Mr. Bennett sailed again for Europe a few days after.

Society of Telegraph Engineers and of Electricians.—The next meeting will take place on Thursday, the 23rd inst., at 8 p.m., when the following Paper will be read: "Notes on the Telegraphs used during the Operations of the Expeditionary Force in Egypt," by Lieut.-Colonel C. E. Webber, R.E., president.

The Maxim-Weston Electric Company.—We learn that Mr. Hugh Watt, merchant, of London and Liverpool, has joined the board of this company as managing director. Much useful work is now being done by the company, thanks to the energy of its late manager, Mr. Massey. We hope

Digitized by Google

that this happy state of affairs will be maintained under the new management.

THE TELEPHONE IN ITALY.—The number of subscribers to the various exchanges of the Société Italienne des Téléphones was as follows on the 15th October last:—In Turin 383, Milan 398, Genoa 383, Florence 281, Venice 114, Bologna 166, Livorno 124, Messina 69, Rome 530, Naples 351, Palermo 150, Catania 54, making a total of 3,003.

THE TELEPHONE IN FRANCE.—The Minister of Posts and Telegraphs has decided to erect telephone lines in the following towns:—Roubaix, Tourcoing, Rheims, St. Quentin, St. Etienne, Fourmies, Cannes, and Nice. He has also authorised the Société Générale des Téléphones of Paris to open exchanges in Alger, Oran, and St. Pierre-les-Calais.

A RAID ON TELEPHONES IN PARIS.—The Société Générale des Téléphones has just made a raid in Paris on all persons making and selling telephones, which they assert are infringements of the Edison patent, and has issued a notice warning the public against making, selling, or retaining possession of such telephones unless they have the company's trade mark on them.

NEW SECONDARY BATTERY.—A Belgian contemporary announces some improvements on the Faure battery effected by Messrs. Tamine, a civil engineer, and Arnould, chief engineer of mines at Mons, in that country. The improvements consist in forming the plates of metal wire wound in a spiral form, and placed in sulphate of copper. The felt of Faure is replaced by very thin discs of porous earthenware.

ELECTRIC LIGHTING OF ROPE AND TWINE MILLS.—The extensive mills belonging to Mr. A. Balstone, of Poole, Dorset, were lighted by electricity on Thursday last. Pilsen arc lamps of 2,000 c.-p. were made use of, and notwithstanding the immense amount of machinery in each room we are given to understand that the lighting proved exceedingly satisfactory. The installation was effected by Mr. R. Bayley, of Poole.

ELECTRIC LIGHTING IN LONDON.—The Bermondsey Vestry do not seem to be much impressed with the recent conference of the local authorities of South London on the subject of electric lighting. A member, who acted as the vestry's delegate at the conference, described his impression of the proceedings as "a jumble of figures which came from a man interested in gas shares." The St. Pancras Vestry will apply for a provisional order.

A MICROMETRICAL MACHINE.—*La Nature* for the 11th November describes a micrometrical machine, which has been constructed by M. Perreaux, and which is capable of measuring one 1,500th part of a millimeter. The machine is so delicate that it is impossible to use it excepting during certain hours of the night, when all vehicular traffic has ceased. Some idea of the minute measuring powers of this machine may be gathered when we say that a millimeter is equal to about $\frac{1}{25}$th of our inch.

ELECTRIC LIGHTS IN MILLS.—Electric lights are now extensively employed in the mills at Holyoke, Mass. The Weston Company have 45 lamps in the Hadley thread mill, the Edison Company 95 lamps in the Little Hampden mill, and the Appleton-street mill, owned, like the preceding, by the Merrick Thread Company, is to be wired for 1,000 Edison lamps. The Whiting paper mill has 100 electric lamps, and the Germania mill has used them since August.—*Sanitary Engineer* (New York).

THE VOLTAIC ARC BETWEEN PLATINUM ELECTRODES.—Gassiot found that, even when a combination of 320 Daniell cells was employed, no spark could be obtained between two platinum surfaces connected with the two poles of the battery, although the two surfaces were brought within $\frac{1}{3000}$ of an inch of each other. If, however, the transfer of some material particles be effected between the two surfaces, either by a momentary contact or even by the discharge of a Leyden jar across the interval, the current may be established and the arc maintained with a small number of cells.

THE EDISON COMPANY AND THE CITY AND GUILDS INSTITUTE.—We understand that this company has entered into a contract with the City and Guilds Institute to make an installation with Edison machines and lamps. The arrangements will be carried out under the direction of Professor Ayrton, F.R.S. The conditions are, we believe, especially stringent, so that the success of this installation will be a far greater proof to the public mind than that of an ordinary installation carried out by the engineers of the company. We hope to give full details of this work in an early issue.

CHINA TELEGRAPHS.—In consequence of the dissatisfaction amongst the mercantile community of China, arising from the frequent interruption of the cable between Hong Kong and Shanghai, in which the Eastern Extension Telegraph Company are equally interested with the Great Northern Company, the Eastern Extension Company are anxious to afford the public the benefit of as good a service as exists over the rest of their system, and they have, we believe, determined to at once take steps to arrange for the construction of a new line, either by land or sea, between those important Treaty Ports.—*London and China Express.*

SWAN'S LAMPS IN A FACTORY.—Messrs. Guinness, Son, and Co., of Dublin, have had the looms in their new woollen factory lighted up with Swan's incandescent lights, the current being supplied by a Crompton-Bürgin machine. The result has been so satisfactory that this firm have entrusted an order to Mr. J. H. Greenhill, of Belfast, who supplied the above plant, for the introduction of Swan lights into their extensive offices in connection with the breweries. We understand Mr. Greenhill has obtained the concession of manufacturing the Crompton-Bürgin machines in Ireland, being the first dynamos made in that country.

WIRE FENCING IN THUNDERSTORMS.—During the thunderstorm of Wednesday week five sheep were killed on the farm of Cotland, Tinwald parish, in Scotland. In one field there was a wire fence for a distance of 300 yards. The current had travelled along this, breaking the wooden posts at various distances, and at the end of the fence two sheep were struck and killed. In an adjoining field, separated from the other by a farm road, the fence was a stone wall, with a single wire on the top. This wire was broken, and touched the ground about forty yards from the road. A number of sheep were crouching near the broken wire, and three of them were killed.

THE EDISON SYSTEM IN STOCKHOLM.—The Edison system has been successfully in operation in Stockholm since the 24th of May last. The different points lighted by the system have been visited by the Royal Princes, members of Parliament, the Municipal Council, and various dignitaries of Stockholm and other cities. The café in front of the Royal palace is one of the places thus lighted, and during the summer months its freedom from undue heat has been much remarked upon by the persons visiting it. The lamps and machines were erected by Messrs. Dreyfel and Co., of Stockholm, for the Edison Foreign Electric Company, by whom the plant was supplied.

Digitized by Google

India Rubber and Wire Wanted.—The Great Southern and Western Railway Company (Ireland) invite tenders for the supply, amongst other things, of india rubber and wire for one year. Forms of tender can be obtained on payment of 6d. each from the company's storekeeper at the General Stores, Inchicore, Dublin. Tenders are to be sent to Mr. F. B. Ormsby, secretary, Kingsbridge Terminus, Dublin, by 10 a.m. on the 27th November. The Midland Great Western Railway Company (Ireland) are also inviting tenders for the same goods. Forms of tender can be had at the General Stores, Broadstone Station, Dublin, on payment of 6d. each. Tenders to be sent to the chairman, at the above station, by the 5th December.

Fire Alarms in New York.—Much comment has been caused by the fact that, although there was a special fire-alarm signal-box in the Park Theatre, New York, which was recently destroyed by fire, no alarm was received from it at the central station, and much valuable time was lost until an alarm was given from somewhere else, more than a block away. According to a New York paper, a workman ran to the box in the theatre, broke the glass case, and endeavoured to give the alarm, but he was probably so excited that he failed to push in the button to send the alarm, and now seeks to cast the blame upon the signal-box or the Fire Department. The same authority says that it has been also claimed that the difficulty was caused by the underground wires being out of order.

New Cable Ship.—We announced in a recent Note that the Postmaster-General had contracted with Messrs. D. J. Dunlop and Co., Port Glasgow, to build for the service of the Post Office an iron screw steamer, specially constructed for the laying and repairing of telegraph cables. The vessel will be built from designs by Mr. Joseph H. Ritchie, Fenchurch-street, E.C. The principal particulars of the vessel are:—Length, 240ft; breadth, 33ft.; depth, 20ft.; to be propelled by a pair of engines having cylinders 30in. and 58in. diameter, with a length of stroke of 48in. To meet the requirements of the special work to be performed, the steamer will be fitted with three circular telegraph cable tanks and a double bottom for water ballast, with fittings adjusted to trim the ship as the cable is paid out.

Chutaux's Battery.—This battery is used in London by the Submarine Telegraph Company. It is composed as follows:—The carbon plate is surrounded with fragments of the same substance, and the zinc with silicious sand. A small porous jar, held at the upper part of the cell, is surmounted by an inverted bottle, containing a bichromate solution. This exciting liquid leaks through the small porous jar, moistens the mass beneath, and drains off from the lower part into a second cell underneath the first, and thence into a receiver, in the shape of a bottle. It is here caught, and can be used again once, and even twice. The carbon is vase-shaped, and surrounded by cardboard, which, under the action of the sulphuric acid, becomes pasty, but this does not appear to increase the resistance much. The E.M.F. of the cell is about 2·2 volts.

Bichromate Batteries.—Amongst other recent modifications that have been introduced in these batteries is that of Messrs. Voisin and Dronier. It consists in the use of dry or solid salts, which only need to have water added to them in the cell to render it ready for action. The salts are used in the proportion of one-fourth of the weight of the water. The constitution is, for the sulphate of potash salt: water, 80 grammes; sulphuric acid, 11·80; bichromate, 5·20; sulphate of potash, 3 grammes. When sulphate of soda is used instead of potash, the proportion of bichromate is 5·40, and of sulphate of soda 2·80 grammes. The salt is prepared as follows:—The sulphate is dissolved in the sulphuric acid by heating, and the bichromate added slowly. When cool the mass solidifies, and just before this takes place—that is, when the mass is not quite cool—it is cast into moulds.

Army Post Office Corps.—The Postmaster-General has directed that the following memorandum from Lieutenant-General Sir Garnet Wolseley, G.C.B., late Commander-in-Chief of the British forces in Egypt, shall be published for the general information of the officers of the Department:—"I have much pleasure in bringing to the notice of the Secretary of State the admirable manner in which the Post Office Corps discharged its duty in Egypt. Their discipline was excellent, and the officers, non-commissioned officers, and men carried out the important duties entrusted to them throughout the campaign in a manner which left nothing to be desired. Their services have been so valuable that I hope a similar corps may be employed on any future occasion on which it may be necessary to despatch an Expeditionary Force from this country.—(Signed) G. J. Wolseley, A.-G."

Electric Light in a Stockport Mill.—Messrs. R. M'Clure and Sons, of Travis Brook Mill, Stockport, partially lighted their weaving shed last winter with the electric light. A 16-light Brush machine, with 16 lamps, each of 2,000 candle-power, was used for the purpose, and the result was so successful that they decided to complete the lighting of their shed, and also to extend it to other portions of their mill. For this purpose they have now had erected a 40-light Brush dynamo with 40 Brush lamps, 31 of which are now in the weaving shed and the remaining nine in the engine house and other rooms. The whole of these were set running a few days since and burnt satisfactorily. The installation has been carried out by the Hammond Electric Light and Power Supply Company, Liverpool, under the superintendence of Mr. James Shaw, the district manager, and Mr. Rowley, electrician to the company for the district.

Overhead Wires in Providence (America).—The Providence *Journal* is reminded by the obstacles placed by telegraph wires in the way of setting up ladders at a recent fire, that an ordinance was passed by the City Council in July of last year providing "that all telegraph, telephone, and other wires now stretched in any street, square, lane, or alley in the first building district below the tops of buildings shall be forthwith removed from such position, and be so readjusted and relaid that the same shall hereafter be stretched and maintained above the top of said buildings." This has never been enforced, and now the Chief of the Fire Department thinks that wires should not be allowed to be placed more than 30ft. from the ground nor less than 20, and he would not allow them to be run diagonally across streets. Where it is necessary to cross streets, wire should be run directly over from poles set on the outer corners.

Overhead Telegraph Wires.—In the House of Commons on the 9th inst. Sir H. Tyler asked what progress had been made during the present year in reducing the numbers of Post Office overhead wires in the metropolitan area, and the numbers and lengths of such wires on the 1st January, 1st July, and 1st November, 1882, as well as the numbers and lengths of wires laid underground at the same periods within the same area. Mr. Fawcett said he had informed the hon. member in June last year that in the March preceding the number of underground wires within a radius of four miles was 4,388, as against 500 overhead. Since that time the underground wires had increased to 4,953, and the over-

Digitized by Google

head wires to 515. Taking a radius of one mile from the Post Office, he found the proportion of underground to overhead wires was 1,822 miles underground, as compared with 58 miles overhead. By far the greater number of overhead wires belonged to telephone and other companies, and not to the Post Office. In one thoroughfare of 97 overhead wires only three belonged to the Post Office.

Danger from Exposed Electric Light Wire.—"A. I. C. E." writes to *The Times* of 13th inst. as follows:—"Your paragraph in *The Times* of Nov. 9 is not an instant too soon. Doubtless in England also we shall have to wait for legislation until, to use your own words, 'some dreadful accident occurs to arouse public indignation.' Meantime, public opinion, if freely expressed, may do something. It is no secret that more than one theatrical manager has in contemplation, or has already decided, to employ the electric light in the coming Christmas pantomimes or extravaganzas as a personal ornament for their hobgoblins and fairies. This can only be done by means of some form of accumulator carried by, or attached to, the individual, and whether the star light is to form an ornament for the head, or to glisten at the end of a wand, the constant danger is patent. There is no need to be an electrician to understand this. A grave responsibility will be incurred by those managers who permit it—a still graver one by those who force it on their *employés*. The life of even a super at 20s. a week ought not to be placed in jeopardy by that autocratic production of our time, the theatrical manager, even if both are willing to run the risk."

Electric Lighting in Brighton.—Mr. Magnus Volk of the Ditchling Rise Telegraph Works, Brighton, has fitted his works with Edison 8-candle lamps, and his house with the same lamps combined with Swan 16-candle lamps. The current is derived from a D^5 Siemens machine wound to give 55 volts, driven by a 2 h.-p. Otto gas engine. Mr. Volk is also engaged in fitting up Messrs. Wallis and Hack's warehouses and shop in the same town, with 20 Swan lamps of 20 candle-power, and 10 of 10 candles. These will be supplied with current by a D^7 Siemens machine, driven by a $3\frac{1}{2}$ h.-p. Otto gas engine. On the 2nd instant the King's apartments in the Royal Pavilion were successfully lighted with incandescent lamps, comprising 25 Edison 8 candle-power, 10 Swan 20 candles, and 8 ditto 10 candles. The current was supplied by a D^7 Siemens machine, driven from the large steam roller belonging to the corporation. Several shops employ the Brush system, some having the lamps inside the rooms, but the majority preferring to utilise them for the illumination of the street in front of their windows. The light given is very brilliant, and when on a visit to the town a few days since we remarked that it was much steadier than has been the case with some other lights on the same system which we have noticed.

Electric Lighting in the Country.—The Sheffield Town Council have received the draft provisional order to enable them to supply electricity in the borough which their Electric Lighting Committee have had prepared.—Weymouth Town Council held a meeting the other day to consider what should be done as to a provisional order, but, after some desultory talk, separated without arriving at a decision.—The St. Helen's (Lancs.) Town Council have decided to obtain a provisional order.—The Ilkley (Yorks.) Local Board think that the information to be obtained from the various companies and other sources as to cost of plant and the vagueness of estimates when submitted are so unsatisfactory that the question of applying for an order, or adopting the light, had better be deferred for the present.—The Airedale (Yorks.) Association of Local Boards, after listening to a paper on the Electric Lighting Act by Mr. Topham, of Tong, could not come to a conclusion, but from the tone of the discussion the general body of the members appeared to think the question somewhat unripe at present.—The Aylesbury Local Board do not think it desirable to apply for an order, nor are they inclined to support a member who proposed to set up an experimental installation in his own house, at a cost of about £3,000, to show what the electric light could do.

A Telephone System for Spain.—A correspondent of the *Bulletin de la Compagnie Internationale des Téléphones* sends the following information relating to the tenders sent in for a concession permitting the establishment of telephone lines in Spain. The tenders were as follow:—(1) Don F. Ayler, representing an English company, offered to work the lines for 20 years, fixing the amount of each subscription at 400 pesetas per annum, 50 centimes for each message sent, and offering 10 per cent. as rent to the State. (2) Don Arturo Soria offered the State 60 per cent. for a concession of six years. (3) Don Emillio Rotondo y Nicolau offered, for 15 years, 250 pesetas per annum, 25 centimes per message, and 12 per cent. for the Treasury. (4) Don Raphael Ruig y Gomez, acting manager of the Compagnie Générale de Téléphone Force et Lumière Electrique, for 15 years at 210 pesetas per year, 19 centimes per message, and $25\frac{1}{2}$ per cent. for the State. (5) Don Tomas Dalman, acting manager of the Compagnie Espagnole d'Electricité for 20 years, 240 pesetas per subscriber per year, 25 centimes per message, and 21 per cent. for the State. (6) Don Carlos A. Bertol, representing a foreign company for 20 years, 25 centimes per message, and 10 per cent. for the State. (7) Don Magin Vilasegart, for 15 years, 200 pesetas per year per subscriber, 20 centimes for each message, and 30 per cent. for the State.

A Medical Opinion of the Electric Light.—Before the electric light becomes, as it must soon become, the common illuminating agent of the period, says the *Lancet*, a determined effort should be made to devise some mode of mitigating its peculiarly unpleasant intensity. The vibratile impulse of the electric force is obviously stronger than the delicate terminal elements of the optic nerve in the retina can bear without injury. We are wont to apply the adjectives "hard" and "soft" to light, and their significance makes them peculiarly appropriate. The electric light is too hard; it needs to be softened. The waves of motion are too short, and the outstroke—so to say—joins the in-stroke at too acute an angle. This might doubtless be obviated by employing suitable material for globes and shades, but perhaps the best plan would be to break up and scatter the rays of light by reflection. If a small convex reflector were placed immediately below the light in the protecting globe, and one of larger dimensions above it, so as to secure a double reflection with ultimate divergence downwards and outwards, the effect would be to cause the "rays" of light to fall obliquely on all objects within the immediate area of illumination. This would, perhaps, obviate the need of coloured glasses, which the promoters of the electric light seem to dislike. Certainly there is a considerable sacrifice of power in the use of the opaline globe—so much, indeed, that some of the districts lighted by electricity displayed through this medium do not present any obvious superiority over gas. We throw out the suggestion for what it is worth. Something must be done, for, as it is, the electric light is "trying to the eyes," which means that it is in danger of injuring them, and already there is reason to believe mischief has been wrought by its use. For true comfort there is nothing like the light given by the old-fashioned pure wax candle.

THEORY OF MAGNETO AND DYNAMO MACHINES.

XIX.

Modern Siemens Armature.

Return to the duplicated Siemens armature represented on p. 437, and instead of doubling its commutator and making, in fact, a double machine, let it only have a simple split ring commutator, as in Fig. 1 of the present article. The ends of the wire of the two coils, *a a* and *b b*, can be connected up as shown in Fig. 1 or Fig. 2., the consequence of which will be that the two coils are in multiple arc, and the E.M.F. in a uniform field will be $\frac{1}{2}$ (sin θ + cos θ), just as it was in the Brush mode of connection, only that now neither coil will be cut out of the circuit at its neutral position, a disadvantage which is more than compensated when many coils are employed instead of only two.

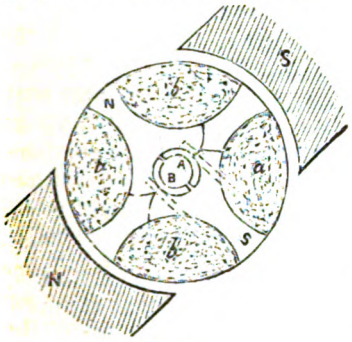

Fig. 1.

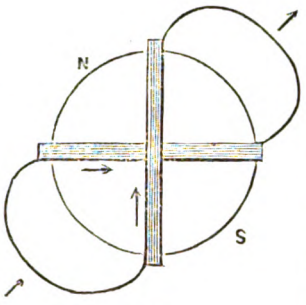

Fig. 2.

To represent the essential parts of Fig. 1 in a simple fashion, suitable for a larger number of coils, is the object of Fig 2. The two coils are shown wound over the front face of the rotating drum, and the free ends of the wire of the coils are connected together as shown, and are understood to be connected also with the two portions of the commutator. The arrows represent a direction of current, such as might be produced by rotating the drum in a magnetic field, or such as might cause the rotation of the drum if sent round it from a battery. The letters N S in Fig. 2 refer to the direction of the magnetic axis, caused by the currents flowing along the arrows.

In Fig. 1 is shown one position of the poles of the field magnet and of the springs or brushes of the commutator, but inasmuch as these are fixed while the armature and commutator rotate, all that is essential about them is that the line joining the brushes should coincide with the line joining the field magnet poles. The position shown, however, is that of maximum action.

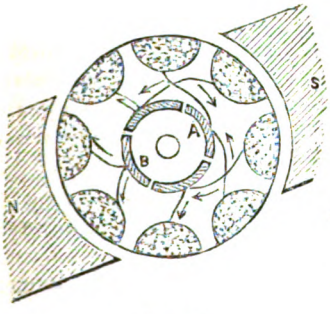

Fig. 3.

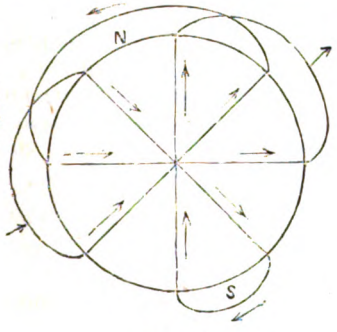

Fig. 4.

[The same is true of Fig. 2, Art. XVIII., representing the Brush mode of connection, which see and compare.]

To generate the currents indicated by the arrows in the given field we should have to rotate the armature against the hands of a watch, thereby moving the induced N pole from the fixed S toward the fixed N. Under these circumstances the brush which touches the commutator segment marked A is the positive one, from which the induced current starts into the outer circuit.

But in order to send these same currents (indicated by the arrows) through the armature from a battery, B must be made the positive pole by connecting it with the platinum end of the battery, and the rotation thereby produced will be like that of the hands of a watch.

This is in obvious agreement with Lenz's law, which says that the induced current must be in such direction as to oppose the motion.

If, instead of sending the current from a battery along the arrows, we chose to make A the positive pole for this case also, then the battery currents would oppose the *currents* produced by induction, but would tend to assist the *motion* producing them.

A little thought will make all this quite clear, but we will just recapitulate. Under the condition of things shown in Fig. 1, provided it is understood that the currents start down the *front* of the drum as indicated in Fig. 2, the following circumstances hold:—

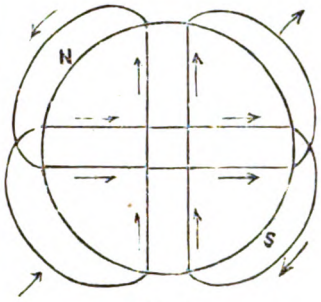

Fig. 5.

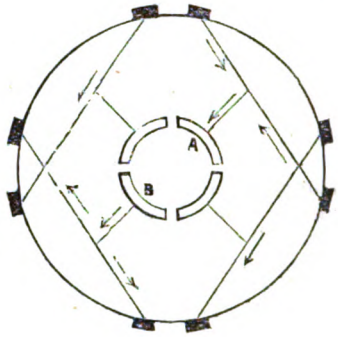

Fig. 6.

Counter-clockwise rotation will develop the arrow-shown currents, and A will be the positive brush;

The positive pole of a battery applied to A will send currents against the arrows, and will cause counter-clockwise rotation;

The positive pole of a battery must be applied to B to send the arrow-shown currents, and the rotation will then be clockwise, as is obvious by looking at the letters N N S S.

Four-coil Armature.

Now consider the drum wound with four coils, the windings being carried right across the axis, as shown in Fig. 4, where the *front* of the drum is again intended to be represented. The commutator must now be a tube split into four segments, as indicated in Fig. 3. The connections of the free ends of the coils must be made as shown in Fig. 3 or Fig. 4; the former showing more explicitly the connection with the commutator segments, which, however, is readily understood in Fig. 4.

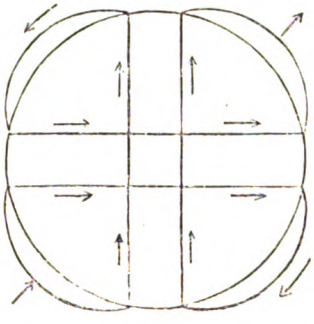

Fig. 7.

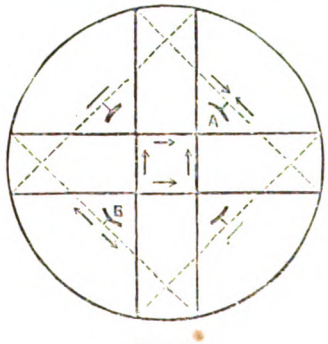

Fig. 8.

The arrows, again, show a possible system of currents, such as would be produced by a battery, of which B was the positive pole, or by a counter clockwise rotation in the magnetic field of Fig. 3, A being the positive pole for the thus induced current. Everything said about A B and N S and direction of rotation remains true; but, in addition, there are two other segments of the commutator which are idle until they are turned into the position of A B, or so near this position that the brushes rest upon them, in which case they *become* A and B.

To understand why the induced magnetism is represented in Fig. 4 in the direction N S, we must apply Ampère's rule

Digitized by Google

to the currents, remembering that they are meant to be flowing in front of the drum, and it will be seen that N S is the *resultant* line of magnetisation for the four coils.

But the method of connection is obviously unsymmetrical and unsatisfactory, and, though no fault can be found with it electrically, a symmetrical system would be more easily recognised as correct. No symmetrical system can however be made so long as the coils are wound singly over diameters of the drum.

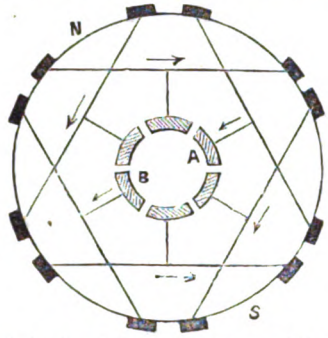

FIG. 9. NOTE.—The horizontal arrows at top and bottom of this figure should point to left, not to right.

The coils must either be wound doubly, *i.e.*, with two wires side by side—in which case, however, it will no longer be a four-coil armature but an eight, and the commutator will have to have eight segments—or the coils must be wound in parallel pairs, as indicated in Fig. 5. This not only gives symmetry, but it is also more easy to carry out in practice, as it leaves a natural space for the axle of the drum. The connections may now be made in either of the three ways repre-

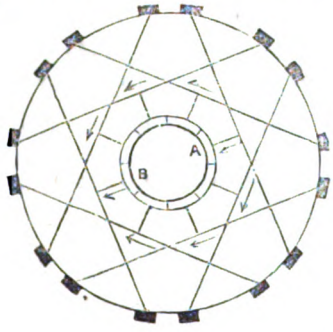

FIG. 10.

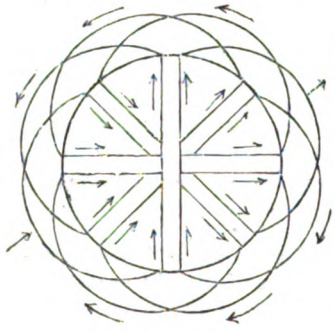

FIG. 11.

sented in Fig. 5, 7, or 8, which are, to all intents and purposes, the same. Fig. 6 is another method of representing the system Fig. 5, and it is, perhaps, the clearest and best mode of representation, all that is left to be understood being that the arrows represent the currents coming from or going to the front portions of the coils, a thing which is shown better in Fig. 5. In Fig. 8 the connections with the commutator are diagrammatically indicated, and the arrows are con-

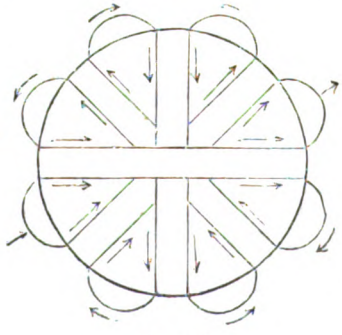

FIG. 12.

sistent in the whole series of Figs. 3 to 8. We may take Fig. 7 as the simplest type and proceed now without the slightest difficulty to the corresponding mode of connecting up a 6-coil armature with its 6-fold commutator, Fig. 9. An 8-coil armature is shown in Figs. 10 and 11, which are identical.

In all these figures A is the positive pole of the machine, if the arrows represent induced currents; moreover, it will be observed how all the arrows are flowing back from A to B past all the idle segments of the commutator. This is essential, and if any pair of these arrows were inverted it would mean that the mode of connection attempted was wrong.

Nothing is easier than to devise such an erroneous mode of connection, and for the sake of instruction an erroneous 8-coil armature is shown in Fig. 12. If a current were sent along the arrows in such an armature there would only be a feeble induced magnetisation, for one of the coils is opposing the other three, but what there was would still be along the line N S, and the machine so wound would still act, though only in a weak and wasteful way.

THE RELATIONS BETWEEN MAGNETIC FORCE AND ELECTRIC CURRENT.—I.

BY OLIVER HEAVISIDE.

Every one knows that electric currents give rise to magnetic force, and has a general notion of the nature of distribution of the force in certain practical cases, as within a galvanometer coil, for example. Further than this few go. The subject is eminently a mathematical one, and few are mathematicians. There are, however, certain higher conceptions, created mainly by the labours of eminent mathematical scientists, from Ampère down to Maxwell, which are usually supposed to be within the reach of none but mathematicians, but which I have thought could be to a great extent stripped of their usual symbolical dress, and in their naked simplicity made to appeal to the sympathies of the many (like Phryne to her judges, perhaps, but I don't remember what she was up for). Let not, however, the reader (if he belong to the many) imagine that thinking can be dispensed with; there is no royal road to knowledge, and hard thinking and rigid fixation of ideas is required. Even the machinery of the mathematician, so great an assistance when made to work, requires severe training on the part of the operator to make it work. But earnest students, if they will not or cannot learn the mathematical methods, need not therefore be discouraged, for the name of Faraday will shine forth to the end of time as a beacon of hope and encouragement to them. He was no mathematician, yet achieved results apparently only attainable by such methods. It need not be supposed that he had the peculiar brains of a calculating boy, able to do long sums "in his head" by special methods of his own. The work was of quite a different kind, and probably Faraday could never have made an ordinary mathematician with the best of training. In fact, mathematical reasoning does not necessarily involve any calculating in the usual sense, though it is, of course, greatly assisted thereby sometimes; and as for the use of symbols, they are merely a sort of shorthand to assist the memory, which even those who openly contemn mathematical methods are glad to use so far as they can make them out, in the expression of Ohm's law for instance, to avoid spinning a long yarn. In the following no symbolisation much more complex is used. Portions in [ ]'s are digressions, not absolutely essential for continuity.

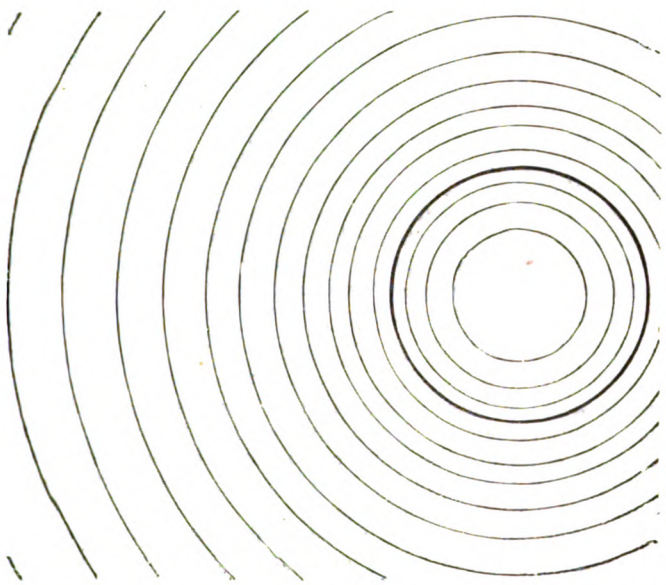
To introduce the subject, we start with the case of a long, straight cylindrical wire, conveying a steady current C. The magnetic force is known to be of strength $\frac{2C}{r}$ in electromagnetic measure at distance r from the axis outside the wire, and its direction to be perpendicular to r and to the axis. This, however, does not settle in which direction along the perpendicular the force acts, and so a rule becomes necessary. Look along the axis in the direction the current is going, the magnetic force is then in the direction of right-handed rotation about the axis. This rule, or any equivalent one, is the key to all the directional relations in electromagnetism. The hands of a watch, viewed from the front (they cannot be seen from the back) revolve right-handedly, so that if we imagine the watch-face to be a section of the wire, and the current to go from face to back, the magnetic force is in the direction of the rotation of the hands.

The force being of the same strength at the same distance

Digitized by Google

from the axis, a line of force is a circle embracing the axis, and the axis is perpendicular to its plane. Confining ourselves now to a single plane normal to the axis, all circles centered upon the point where the axis cuts the plane are therefore lines of force. But if we wish to show graphically the strength of force as well as its direction at any place, the best way is to draw the lines so that their density or closeness together shall be proportional to the strength of force at the place. In our present case this gives us the rule that the radii of successive circles should increase geometrically.

Within the wire, the magnetic force is known to be of strength $\frac{2\,Cr}{a^2}$ at distance r from the axis, a being the radius of the wire, and, like the external force, perpendicular to r and to the axis, with right-handed rotation. At the surface, the two expressions become the same, viz., $\frac{2\,C}{a}$. The force being now directly as r, a different rule is required to make the density of lines of force proportional to the force. The squares of the radii of successive circles must form an arithmetical progression. Further, the scale outside and within should be the same, so we require a relation between the common ratio of consecutive radii outside, and the common difference of squares of consecutive radii within. [If ρ is the external ratio and d the internal common difference, $d = 2\,a^2 \log.\ \rho$. For let a_1 be the radius of first circle outside, and a_0 that of first inside, a_0 a and a_1 being thus consecutive, we must have, k being any constant,



$$\frac{k}{a_1 - a} = \frac{1}{a_1 - a} \cdot \int_a^{a_1} \frac{2\,C\,dr}{r} \therefore k = 2\,C \log.\ \frac{a_1}{a} = 2\,C \log.\ \rho$$

$$\text{Also, } \frac{k}{a - a_0} = \frac{1}{a - a_0} \int_{a_0}^{a} \frac{2\,Cr}{a^2}\,dr \therefore k = C\,\frac{a^2 - a_0^2}{a^2} = C\,\frac{d}{a^2}$$

Therefore, $d = 2\,a^2 \log.\ \rho$.]

In the figure, the common difference d is chosen $= 1$ and the radius $a = 2$, so that the three lines within the wire (which is bounded by the thick circle) have radii 1, $\sqrt{2}$, $\sqrt{3}$. The circle $a = \sqrt{4}$ is also a line of force, and the rest have radii 2ρ, $2\rho^2$, $2\rho^3$, &c., where $1 = 8 \log._\epsilon \rho$.

Let us now examine a general property of this system of magnetic force. If we place a unit magnetic pole at any point in the external field, and suppose that it can move freely under the influence of the magnetic force of the current, and that no other forces act upon it, the pole will evidently describe a circle about the axis, and the work done by the force on the pole during a complete revolution will be force $\times$ distance $= \frac{2\,C}{r} \times 2\,\pi\,r = 4\,\pi\,C$. And evidently in moving through any stated fraction of the complete circle, the work will be the same fraction of $4\,\pi\,C$. Observe that this is the same at any distance from the wire, and the work depends only upon the angle turned through. Also, if the pole be moved either radially from the axis, or parallel to the axis, there is no work done, because there is no force in those directions. Let now the pole be carried from any one place to any other by any path, its motion at any point of the path may be compounded of a motion *from* the axis, a second *parallel* to it, and a third *round* it. Since the last alone involves the performance of work it follows that the work done on the pole between any two points by any path is $2\,C \times$ angle turned through in the positive or right-handed direction, between the first and last positions.

Now, limiting our consideration to motion in completely closed paths, if the curve embraces the wire once, the line integral of the force once round the closed curve is $4\,\pi\,C$, and if it goes round n times (in + direction) it is $n \times 4\,\pi\,C$. But if the closed path does not embrace the current, or if embracing it a certain number of times in the + it embraces it the same number of times in the — direction, so that if the path were a string it could be drawn off the wire without cutting it, the line-integral is *nil*. In this case the angle turned through about the axis comes to nothing when we return to the starting-point.

Transferring our attention next to the current passing through the closed curve, we see that when the line-integral is *nil* the current is *nil*, and when the line-integral is $4\,\pi\,C$ the total current through the curve is C, and when it is $n \times 4\,\pi\,C$ the total current is $n\,C$. This may be all summed up in one statement. The line-integral of the magnetic force once round any closed curve equals $4\pi \times$ total current through the curve.

Let us now see whether the force within the wire follows the same rule. First let the unit pole follow a line of force once round the axis at distance r. The work done by the force = force $\times$ distance $= \frac{2\,C\,r}{a^2} \times 2\,\pi\,r = 4\,\pi\,\frac{C\,r^2}{a^2}$. Now, $\frac{C}{\pi\,a^2}$ is the current density, and $\pi\,r^2$ is the area enclosed by the line of force, so that $\frac{C\,r^2}{a^2}$ is the current through the closed curve, and, as before, line-integral of force $= 4\,\pi \times$ current enclosed. And, since there is no force parallel to, or radially from the axis, the same statement is true for any closed path whatever within the wire; and, being true outside the wire, is also true for any path partly within and partly without, and so, in fact, is universally true.

Now we shall generalise the statement. It is not merely true for the magnetic force of a straight current, but also for any possible system of magnetic force. It is the fundamental relation between magnetic force and electric current. Given, then, a system of magnetic force, we may find the corresponding current system by the following process. Required the current at any point, P. Through P draw any straight line, and describe a small plane closed curve about it as an axis. Find the line-integral of the magnetic force along the curve once round the axis, or the work done upon a unit pole during one rotation. The result is $4\,\pi$ times the current through the curve. Divide by the area enclosed, and we obviously get $4\,\pi$ times the component of the current density in the direction of the axis.

Let the axis turn about the point P as fulcrum into any other position, the closed curve moving with it as if rigidly attached; the line-integral in the new position will be $4\,\pi \times$ current through curve in the new position. There is a certain direction of the axis for which the line-integral is a maximum; this direction is that of the actual current at P, and the maximum line-integral divided by $4\,\pi$ times the area is the actual current density. We may conveniently take the area for unit area, so as to get the current density at once. Or, we may find the current density by the above process in any three rectangular directions, and their resultant will be the actual current density.

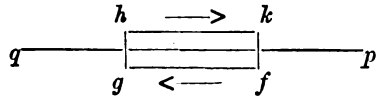
This process, by which we derive current from the magnetic force, is of great importance in physics. Especially so in electro-magnetism, where there are several quantities bearing to one another the same relation. When one vector or

Digitized by Google

directed quantity, B, is related to another vector, C, so that the line-integral of B *round* any closed curve equals the integral of C *through* the curve, the vector C is called the curl of the vector B. The term curl was proposed by Maxwell, though he does not appear to have used it much. Its appropriateness is evident on considering the method by which we derive C, the curl of B, from B itself; and, as a name for the operation is wanted for descriptive purposes, it will be used in the following. Thus, current $= 4\pi \times$ curl of magnetic force.

[The presence of the factor 4π is due to the definition of a unit magnetic pole. If we defined the unit pole so that the unit amount of force emanated from it, the force at distance r would be $\frac{1}{4\pi r^2}$, since $4\pi r^2$ is the area of the spherical surface over which the force is spread at distance r. Then we should have current = curl of magnetic force. And if we had a similar definition of the unit of free electricity, we should have the electric force at a surface numerically equal to the surface density, instead of, as at present, 4π times as much. But the actual definitions chosen make the force at distance $r = \frac{1}{r^2}$. This looks simpler, but it leads to the awkward result that mathematical investigations, both in electrostatics and in electro-magnetism, are filled with 4π's, and $\frac{1}{4\pi}$'s. Sometimes we multiply, at other times divide. They would mostly be got rid of by defining electric and magnetic forces as fluxes in the same manner as the electric current, for a current, C, spreading from a centre produces current density $\frac{C}{4\pi r^2}$ at distance r, and not $\frac{C}{r^2}$. At the same time, 4π would make its appearance in certain cases where it is now absent, such as in spherical problems, and its presence there would be perfectly natural, 4π being the area of unit sphere.]

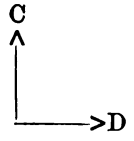
To show that the idea of the curl is not without practical utility, even to non-mathematicians, we may employ the process to find the distribution of current for fresh systems of magnetic force, starting from the one already treated. Call the magnetic force of a straight current B, and the current C, this being now the current density. We know that $4\pi C =$ curl of B. What is next the curl of C? This is easily found. Outside the wire C is *nil*, therefore so is its curl. Within the wire C is uniform, so that its curl is also *nil* there. But in passing through the surface, C suddenly changes from C in the wire to 0 outside, so there *is* surface-curl. Let



pq be a straight line upon the surface in the direction of C. Let the closed curve of integration be the rectangle $fghk$, consisting of two straight lines fg and hk parallel to the surface, and very near it, with two connecting pieces gh and kf; and let the rectangle be perpendicular to the surface. We have to find the line-integral of C once round $fghk$. Evidently the portion fg contributes $fg \times C$, and the rest nothing; the connecting pieces because they are perpendicular to C, the other because it is outside the current. $fg \times C$ is, therefore, the total amount of the curl of C passing through the rectangle, *i.e.*, it is of strength C per unit of length along pq. Shorten the connecting pieces indefinitely, we have still the same result, so that the curl of C is finally a vector quantity of amount C per unit of length of pq, drawn upon the surface at right angles to the current. Let the current go from right to left, then its curl is directed downwards through the paper, that is, in the same direction as the magnetic force. The same is true for every point of the surface, so that the lines of the curl of C are circles upon the surface, centred upon the axis.

Let, now, C represent the magnetic force in a new system, *i.e.*, the magnetic force is confined to the space within a long cylinder, and is everywhere parallel to its axis, and of uniform strength C. We have found the curl of C, so we know the corresponding current distribution. It consists of a cylindrical current sheet, the current circulating round the axis, its amount per unit length of cylinder being $\frac{C}{4\pi}$. This is the case of a long solenoidal coil of a single layer of wire; if the current per unit length be C, the magnetic force is *nil* outside, and of uniform strength $4\pi C$ within, parallel to the axis. Put on more layers of wire, and we have simply to add on the additional magnetic force, and the result is that the magnetic force is $4\pi C$ (where C is the *total* current round unit of length) everywhere inside the innermost layer, and falls from $4\pi C$ to 0 in passing through the layers to the external space.

For another example, let us find the curl of the current in the last case. Start with a cylindrical current of strength Ct per unit length, and let the small thickness of the current layer be t, so that the current density is C. We found before that to deduce the curl of a vector C when it suddenly changed from C to 0 in passing through a surface, we had merely to turn it through a right angle upon the surface, and we obtained the new vector. The direction of rotation must, however, be carefully attended to. If we look down upon the surface, and the direction of C is as shown, then its curl, D, goes from left to right. Now our current sheet has two surfaces, inside and outside. In passing from the current to outer space, we therefore rotate one way through a right angle, thus bringing us parallel to the axis; and in passing from the current to inner space we rotate the other way through a right angle, bringing us also parallel to the axis, but pointing in the reverse direction. Since we get the same result everywhere, the curl of C consists of two tubular vector systems separated by the thickness t, of equal strength, but oppositely directed.



If, then, C represents the magnetic force in a new system, we have the following:—Two thin concentric tubes, distance between them $= t$, a current of total strength

$$C \times \frac{2\pi a}{4\pi} = \frac{Ca}{2},$$

where a is the mean radius of the tubes, straight along the outer tube, returning by the inner one. There is no magnetic force within the inner or without the outer tube. Between them, the magnetic force is in circles about the common axis, and is of mean strength C.

Further application of the same process only gives rise to repetitions in a more complex form of the last two examples, multiplications of cylindrical and straight tubular currents alternately, and we need only notice the first of the series. If we find the curl of the current in the last case, and then transform current into magnetic force, we obtain four cylindrical current sheets. In the outer and innermost the current circulates round the axis one way, in the two intermediate the other way. The magnetic force is parallel to the axis between the first and second, and also between the third and fourth, but oppositely directed, and is *nil* everywhere else.

We see that the process of deriving fresh distributions from a known one by curling may be continued. We have a series of vector systems, A B C, &c., of which any one is the curl of the preceding; and, taking any one to represent magnetic force, the following one is the corresponding current, excepting a constant factor. It will readily suggest itself that the series may be continued the other way. This is true, but is not so easily managed. The reverse operation to finding the curl of a vector, viz., to find the vector whose curl is a given vector, is more difficult than the direct, though of not less interest or importance. This matter, and some other relations between current and magnetic force, will form the subject of a following article.

CURRENT FORCE AND ENERGY.—II.

BY JOHN T. SPRAGUE.

(CONTINUED FROM VOL. IX., P. 584.)

It was not sufficiently explained in the article, p. 583, Vol. IX., that the definition of *force*, as representing the *square root of energy*, applies to the *potential* energy, not to energy developed, and that it refers also to unit conditions, that is to say, to force acting in a unit conductor. Here the hydraulic and electric analogy fails to some extent. We can have a water current without a conductor. The unit conditions stated, of a stream issuing from an opening of one circular inch, involve no conductor and no resistance, and the issuing stream carries with it the energy due to its velocity. But a conductor is essential to the electric current, and the energy is wholly expended in the circuit (for even external work constitutes a part of, or a condition of the circuit itself). We are, therefore, compelled to work under the consequent limitations. The result is that with "head of water" we can never have a current greater than the rate due to force. But in electricity we can, and then the energy developed will be greater than that potential in the force. This results from the fact that gravitation is a real force, while E.M.F. is an artificial one, of which the consideration of unit resistance is an integral part. It is only the theoretical force capable of sending unit current through unit conductor.

The proportion of energy which becomes developed as work is as $E^2 \div \frac{E}{R^2C}$, which comes to $E^2 \div R$, and the reason is that the true resistance, which varies as the square of C in any conductor, may be regarded as a counter, or — E.M.F., because it reduces current or velocity. This is clearly recognised in hydraulics where frictional resistances are reckoned in terms of the head of water absorbed in overcoming them. A glance at the table, p. 583, will show this, and explain how part of the energy due to "force," as expressed in terms of square root of head, becomes kinetic and the rest remains potential. If we take for unit such an opening as allows 1lb. water per second to issue under unit force we should have 3lb. under $M \div 3$, line 3, which gives Col. VI. $144 \times 3 = 432$ft.-lbs. of energy, or 27 units. If we now add piping such as will reduce the current to 1 we have only 1lb. falling 144ft., which is 9 units of energy kinetic. Now, although the current is only that due to M 1, we cannot express the action as due to $M\,3 - 2 = 1$, because this would only give us 16ft.-lbs. or 1 unit kinetic energy; but we have 9 units, and the difference between 1 and 9 has disappeared in the form of friction in the pipe, converted into heat. The same occurs in electricity; but, as just remarked, the conditions are somewhat different, and we must look further before we find what expression of the vanished energy can be used as — force or as resistance.

We have brought the water current to conditions closely analogous to those of the electric current, and to Ohm's formulæ, but we require something which will represent the electric circuit. There is a great difficulty here, because while the conductors agree in both cases by varying as their areas, this is not so as to the work expended in them as friction or heat. In pipes this is two fold. 1. Skin or surface friction, varying as the surface, that is as *square root of area*. 2. Viscosity of the water itself, which necessarily varies as the *area*. Both vary also as the length and as the square of the current or velocity. In wires there is only one friction or energy expended in molecular motions, and this is as the area simply, and the same as with water as to length and current. This difficulty may be partially overcome by considering any increase of conductor in the same manner as it is wise to consider wires; to disregard actual sizes, but to consider any increase as meaning so many unit conductors added, that is, in order to double the area of the water current from a 1 inch pipe, instead of increasing the pipe to 2 circular inches (that is a diameter of 1·4 inch), we must insert a second inch pipe, side by side, carrying the same current, and expending the same energy as the first. In the same way we should consider wires, not as to their gauges and diameters, but by the number of unit wires of 1 mil. circular ($\frac{1}{1000}$ of an inch) to which they are equivalent, which is in fact their area in circular inch as given by d^2. We must now add a definition of length to constitute a conductor of unit capacity in order that we may include the resistance as friction, &c., essential to the passage of current, and upon which, therefore, the conducting capacity will depend.

Resistance.—The definition of Ohm's law is that current is proportionally as the force, and inversely as the resistance. $C = E \div R$. What is resistance? Common sense, universal mechanical experience reply *that which resists*, that is to say which stops or diminishes motion, that which absorbs energy in the overcoming it. These two definitions are the same in fact and in theory, but they can be made to work out in very different fashion. For this reason I put them again distinctly as if different.

Resistance is { (A) that which opposes or reduces current. (B) that which absorbs energy.

Looked at as A resistance is a counter, or force, and as such it must be expressed as $\sqrt{energy}$. Looked at as B it is work, and it must be expressed as simple *energy*.

The *ohm* is the unit of electric resistance; in what way is it related to these definitions? Inasmuch as the ohm is a measure of a part of the circuit, and as a conductor is absolutely essential to the passage of current, and holds to the electric current the same relation as the pipe does to water, it seems we should primarily regard it as a unit *conductor*, not a unit *resistance*; it would be considered absurd to call a pipe a "resistance" to a water current. But if we measure the circuit in terms of conduction, it is evident that, calling the unit conductor A, the formula for current would be $E \times A = C$; but, inasmuch as increasing length would reduce conducting power, the value of A would have to be calculated inversely to its length or number of unit conductors added lengthwise. This would be inconvenient, and, therefore, an arithmetical strategem is employed. The result is the same, whether we multiply by a number or divide by the reciprocal of the number (the reciprocal being 1 divided by the number). Therefore, we may transform A, the conducting capacity, into R, its reciprocal, and then the current formula becomes $E \div R = C$. Now, every conductor absorbs energy in transmitting current, and this is a true *resistance*. We must, therefore, set up a unit value of this energy or resistance in terms of the unit system, that is, this unit must be the amount of energy absorbed by the unit conductor when transmitting unit current. This unit energy, tending to diminish current, is, therefore, in inverse relation to force, and takes its part in the formulæ exactly as does the reciprocal of conducting capacity (which, in fact, is determined in value by the consequent reduction of conducting capacity). Hence the symbol R includes both these; it is the reciprocal of conduction, and it is also the resistance.

But these relations, simple enough and clear as to the unit value, lose their simplicity the moment we pass to larger currents; then resistance in its sense (B) increases in the ratio of the squares. We cannot well divide E, the force which increases as current, by an R, which increases as the squares, to obtain a result (C) proportional to the force and the conducting capacity. To do this we must express this resistance in its (A) sense, that is to say as an inverse or counter force. This means that we must express it by its square root, as with the force. The necessary unit of energy as resistance or work is derived from $C^2 \times R$, and in the electric system it gives us a value in ergs 10^7; in the practical system we have the *joulad* expressed as a power by the volt ampere, proposed to be called the watt. If we symbolise this by J the formulæ gives us—

$$\frac{E}{R} = \begin{cases} C\ \frac{\text{Volt}}{\text{Ohm}} \\ J^2 \end{cases} = \begin{cases} \text{Ampere} \\ \text{Joulad}^2. \end{cases}$$

From these considerations we can define the ohm as a unit conductor, in which unit energy is absorbed when unit current passes, and generally as the square of the current passing. It is a resistance only in a mathematical sense.

When it is stated that in electricity a resistance, say 1 ohm, is the same for all currents, "the same for a circuit working one lamp as for working 100 or 1,000," we are simply deal-

Digitized by Google

ing with mathematical legerdemain. The statement is utterly absurd; no such resistance is to be found throughout nature. It only becomes true when we recognise the "fact that in transmitting electrical energy the conductor itself retains a certain amount proportional to that transmitted, which makes its appearance therein in the form of heat," and the further fact that these energies are not only as the 1, 100, and 1,000, but as the squares of those numbers if the same conductor is used. The common statement, so often made, that electricians look upon it as an established truth, is utterly unmeaning when we consider the ohm as *resistance*. It is explainable when we see that it really means, in the way it is used, the square root of the resistance converted into an artificial counter force, to match the artificial force created from the square root of the active energy.

To carry out our analogy we now require a pipe which shall fulfil for water currents the same conditions as the unit ohm does for electricity. It must be, to carry on the system, a pipe of 1in. circular area of such length as to pass a unit current = 1 gallon per second under unit head 16ft., and it must be of such length and material as to absorb unit energy = 16-foot pounds in friction when unit current passes. Now here we come to a problem more intricate than that of the ohm. The whole energy of unit current in electricity is expended in the unit circuit, because the circuit is a closed circle, and no electricity leaves it, nor has electricity any *momentum*. But a ponderable fluid, as water, has momentum, and as long as we treat the current as derived from a head of water the unit current when it leaves the unit conductor will still retain its unit momentum or force. This is of necessity, because if the unit conductor absorbed the whole energy there could be no current. This can be met by treating the current as due to a hydraulic engine acting upon a closed circle of pipe, but its consequence at present is that we can only define our unit conductor as that which would allow unit current to pass under doubled head, of which one head, 16ft., is employed in giving the final velocity, and the other head, also 16ft., is employed in supplying unit energy, 16ft.-lb., to overcome the resistance. As a consequence, we could not employ for water-currents a single and simple relation like Ohm's formulæ, though the same principle is in operation; we should have to divide it into two parts, one of which would represent the current and its energy in the pipe, and the other the energy carried by the issuing stream. It is only the first part which concerns the electric analogy, and what we have to consider is, what length of 1in. pipe would consume in friction the energy of unit head, that is to say 16ft.-lb., while passing a unit current of one gallon per second; that pipe would also allow the unit current to pass under a double head, because the formula would be $\frac{1M}{1C} = 1C + 1M \times 1A = 1C$, the true resistance or energy absorbed by friction being expressed in the first part exactly as in the electric formula, while the issuing current would be represented by the second. The actual pipe corresponding to this formula would depend upon the nature of its inner surface, but taking the ordinary formulæ for transmission of water through iron pipes, it is approximately one yard of 1in. pipe, which, therefore, corresponds in all respects for water currents to the conductor of 1 ohm resistance for electric currents.

The analogy would be more perfect if worked out for the case of a circulating current from a hydraulic engine with a circuit of piping, but this would not have furnished the evidence that E.M.F. expressed in volts is the analogue of the hydraulic force "square root of head" which was necessary to explain what I mean by saying that these artificial forces are derived from energy. I may add that various writers have worked at the same idea, but have been led in a different direction by giving a different expression to "force." They have claimed that the true electric *force* is the attraction between two surfaces, and they are certainly right, because this attraction is exactly analogous to pressure, and therefore to head of water. But whether we call it E.M.F., or potential, or tension, the volt expresses, not this attraction, but its square root, corresponding to the square root of head of water or static pressure. The result is that the writers referred to call that *force* which does not answer to the definition of force, but which does answer to the definition of *energy*, either under unit conditions, or potential as well as kinetic.

CORRESPONDENCE.

CHARGING SECONDARY BATTERIES.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: With reference to the arrangement by Mr. Kent for giving warning of the reversal of current in charging accumulators, which was inserted in your last number, there is no doubt that it is a very simple one as an alarum for mere reversal. But Mr. Kent does not seem to take into consideration the fact that Mr. Crawley's arrangement, though not entirely self-acting, also gives warning of the weakening or strengthening of the charging current, which is a very great advantage, particularly in carrying out experiments with new forms of cells. Should the current happen to fall below a certain limit, or to reverse, thus allowing the lower spring to make contact and give the alarm, it is an easy matter when altering the current to replace the spring. It is obvious that the top spring does not again require to be touched after having been once set to ring the bell when the current strengthens beyond a given degree. I may add that in practice this instrument can be readily adjusted to show differences of less than half an ampere above or below the proper charging current.—Yours, &c., E. C. RIMINGTON.

School of Electrical Engineering, 12, Princes-street, Hanover-square.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In the letter from me on the above, published in your last, you have omitted the word *or* in line 15. It should be out of bell to earth *or* on to negative pole of first accumulator.—Yours, &c., H. A. KENT.

154, Culford-road, N., November 13, 1882.

ELECTRIC TRICYCLES.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I can assure your correspondent, Mr. MacDonald, that there was no disposition on my part to "chuckle" at the electricians and their tricycles. My letter was written with the simple object of showing the rocks and quicksands ahead, and I can only assure your correspondent that I am very pleased that he has found a practical way out of the difficulty. We have the authority of Dan O'Connell's statement that it is easy to drive a coach and horses through an Act of Parliament, but I think this is the first case of a tricycle being driven through the Locomotive Roads Act. I am sure it would be interesting to your readers if Mr. MacDonald will favour us with a description of the motor he proposes to use, and what his idea is as to the cost of a tricycle fitted according to his plan.—Yours, &c.,

CHANCERY LANE.

ELECTRICAL TRANSMISSION OF ENERGY.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I happened yesterday to be talking to an electrician when the conversation turned upon the experiment of M. Marcel Deprez in "Electrical Transmission of Energy," made at the Munich Electrical Exhibition, and quoted, as I see, in *The Electrician* of Nov. 4th. The gentleman in question was so convinced that the transmission could never have taken place that my hesitation to join at once in his incredu-

Digitized by Google

lity was met by a somewhat contemptuous, but not in such cases unprecedented, reference to "all the text-books on the subject," which I was advised to consult. As further argument was not forthcoming, I determined to find out what real ground there was for rejecting altogether the experiment of M. Marcel Deprez, and to form an idea of the probability of the case as stated being approximately true.

Taking, therefore, the equation of energy applicable to a single-circuit system,

$$C^2 R - C E = - W,$$

in which C is the current, R is the total resistance, E is the electromotive force of the generating machine, and W is the entire work given out by the other machine, all in electrical units. I may remark that in this particular case W = 373 and R = 1900; so that the equation has only two unknowns, C and E, but C is involved to the second power. The alternation of the signs of the terms shows that the two values of C are, when real, both positive. Let us now write the above equation in the following forms:—

$$C = \frac{E}{2R} \pm \frac{\sqrt{E^2 - 4RW}}{2R}. \quad \ldots\ldots\ldots \quad (\alpha)$$

$$1 - \frac{CR}{E} = \frac{W}{EC}, \text{ which is clearly the efficiency.} \quad (\beta)$$

Call the efficiency a.

The equation (α) at once shows that C cannot have a rational value unless E^2 is as large as 4 R W or larger.

If $E^2 = 4RW$, we can find E from this equation,

$$E = \sqrt{4 \times 1900 \times 373} = 1684 \text{ volts about.}$$

In which case

$$C = \frac{E}{2R} = \frac{1684}{3800} = \cdot 443 \text{ amperes.}$$

So that until the electromotive force of the generating machine reaches 1684 *volts, and the current is* ·443 *amperes, the* 373 *watts cannot be transmitted at all through the* 1900 *ohms of total resistance.*

The efficiency $a = 1 - \frac{CR}{E}$, from which, by substituting for C its value in (α), we have

$$a = \tfrac{1}{2} \mp \frac{\sqrt{E^2 - 4RW}}{2E}, \quad \ldots\ldots \quad (\gamma)$$

$\therefore$ the efficiency is $\frac{1}{2}$ in this case of $E^2 = 4RW$.

But we may write this equation (γ).

$$E^2 = \frac{RW}{a(1-a)}, \quad \ldots\ldots\ldots \quad (\delta)$$

which is a convenient form to deduce E when the efficiency is given. Suppose the efficiency is $\frac{60}{100} = \frac{3}{5}$.

Then $$E^2 = \frac{1900 \times 373}{\frac{3}{5} \times \frac{2}{5}} = \frac{1900 \times 373 \times 25}{6},$$

or E = 1718 volts about.

The probability of M. Marcel Deprez's statements being true rests, therefore, upon the probability of his having found a machine to generate the above electromotive forces, which is probably what my friend would say is what he meant all the while.—Yours, &c., THOMAS H. BLAKESLEY.

November 10th, 1882.

LAMPS FOR CARRIAGE.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Could the lamps of a two-horse carriage be lit by electricity, either arc or incandescent light?

I require a very strong light for driving fast on a dangerous road at night, and oil lamps are not bright enough. I should feel much obliged if you will answer this question in your interesting paper.—Yours, &c., W. W.

PHYSICAL SOCIETY—Nov. 11.

Profesor CLIFTON, President, in the chair.

Professor ROWLAND, of Baltimore, exhibited a number of his new concave gratings for giving a diffraction spectrum. He explained the theory of their action. Gratings can be ruled on any surface of the lines, are at a proper distance apart, and of the proper form. The best surface, however, is a cylindrical or spherical one. The gratings are solid slabs of polished speculum metal, ruled with lines equidistant by a special machine of Professor Rowland's invention. An account of this machine will be published shortly. The number of lines per inch varied in the specimens shown from 5,000 to 42,000; but higher numbers can be engraved by the cutting diamond. One great advantage of their use is that the relative wave-lengths try the micrometer with great accuracy. The author has designed an ingenious mechanical arrangement for keeping the photographic plates in focus. In this way photographs of great distinctness may be obtained. Professor Rowland exhibited some 10in. long, which showed the E line doubled and the large B group very clearly. Lines are divided by this method which have never been divided before, and the work of photographing takes a mere fraction of the time formerly required. A photographic plate, sensitive throughout its length, is got by means of a mixture of locene, iodised collodion, and bromised collodion. Professor Rowland and Captain Abney, R.E., are at present engaged in preparing a new map of the whole spectrum with a focus of 18ft. In reply to Mr. Hilgar, F.R.A.S., he stated that if the metal is the true speculum metal used by Lord Rosse it would stand the effects of climate he thought; but if too much copper were put in it might not. In reply to Mr. Warren de la Rue he said that 42,000 was the largest number of lines he had yet required to engrave on the metal.

Professor GUTHRIE read a letter from Captain Abney pointing out that Professor Rowland's plates gave clearer spectra than any others; they were free from "ghosts" caused by periodicity in the ruling, and the speculum metal had no particular absorption.

Professor DEWAR, F.R.S., observed that Professor Liveing and he had been engaged for three years past in preparing a map of the ultra-violet spectrum, which would soon be published. He considered the concave gratings to make a new departure in the subject, and that they would have greatly facilitated the preparation of his map.

Mr. W. BROWN then read a paper on the "Conservation of Energy and Central Forces." He showed that the doctrine of the conservation of energy necessarily involved central forces, and could not be proved unless on the assumption of a system of central forces. This involved the hypothesis of Boscovich, that matter consists of a collection of centres of force, and the author criticised the objections of Clerk Maxwell, Tait, and others to Boscovich's theory. The paper will appear in the *Transactions* of the Society.

Professor S. P. THOMPSON read some "Historical Notes on Physics," in which he showed that the voltaic arc between carbon points was produced by a Mr. Etienne Gaspar Robertson (whose name indicates a Scotch origin) at Paris in 1802. This reference is found in the *Journal de Paris* for that year. Laboratory notebooks at the Royal Institution, however, are said to show that Davy experimented with the arc quite as early. The experiment usually attributed to Franklin of exhausting air from a vessel of water "off the boil" and causing it to boil afresh is found in Boyle's "New Experiments Touching the Spring of the Air." Professor Thompson also exhibited an early Reis telephone, made by Philip Reis in 1861 at Frankfort, and designed to transmit speech. It was modelled on the human ear, one form of transmitter being a rudely-carved wooden ear, with a tympan having a platinum wire behind, hard pressed against a platinum-tipped adjustable spring. Professor Thompson showed by various proofs that words were actually sent by that and similar apparatus.

INDIAN TELEGRAPH SERVICE.—Notice is given that the Secretary of State for India will, in the summer of 1885, offer two appointments in the Indian Telegraph Department to students entering the Royal Indian Engineering College at Cooper's Hill, near Staines, in September, 1883. Candidates for admission to the college must on the 1st of July next be over 17 and under 21 years old, and must give satisfactory proof of having received a fair general education. Further particulars can be obtained by applying in writing to the Secretary, Public Works Department, India Office, S.W., or to the President of the College.

SCIENCE CLASSES EXAMINATION.

The season of science classes is now at its height, and before many months are over we shall see the fruits thereof being gathered. By fruits we mean the results of examinations, which have come to be regarded as the end and aim of all learning, scientific and other. We do not ourselves so regard them, as we have said before on more than one occasion; but such is the current view, and we must take it at its own estimate. If all that is to be got out of science classes were a certain percentage, low or high, of pass certificates and prize awards, then science would, indeed, be in evil case. Happily, it has not arrived at that stage yet, and we believe it never will. But the fact is undeniable that amongst a large number of students the ostensible aim is this, and nothing else but this. At all events, this is the immediate aim, practical and ulterior objects being for the moment subordinated.

That the attainment of these objects is not always furthered, and is sometimes hindered, by a course of study directed to the passing of an examination—or a series of examinations, for there are a great number to compete in—is almost certain; but the prevalence of the system, and the market value of the honours secured under it, compel obedience to its prescribed course, only very adventurous spirits daring to travel by any other road. The fault is not theirs; the system has grown, and is fast taking root, like some novel cult, under patronage of the high priests — who are first shy, then sly, and then among its warmest devotees. The sacred doors of the examination room are supposed to be the portals to fame and a great career. All hope abandon—the presiding geniuses are evermore decreeing—ye that do not enter here; and the crowd grows thicker and thicker who throng the highroad thereto. That many a pilgrim fails to gain admittance who ought to be respectfully welcomed is, perhaps, not much to be lamented. His very demerits, for that kind of scramble, may serve him in good stead hereafter for toil more profitable. But it is to be regretted, and greatly, that many who have no sort of title to enter do enter and pass out, bearing unimpeachable testimonials that they are true sheep when in reality they are but worthless goats. Not until they have done themselves perhaps irreparable injury, and deceived a number of innocent persons besides, is the delusion found out.

We speak of it as a delusion, because it would be unfair to call it an imposture. The imposition, if there is any, is inside the temple, not outside. The wise men know very well by this time that their divinations count for hardly anything; but the oracles are of their own contrivance, and to alter them might shake the very foundations of the faith. Reform from that quarter is therefore not, perhaps, to be looked for; nor do we look for it by means of attacks directed against either the men or the system. There are good points in both. Rather by the results would we test them; not by disparaging the Gods, but by depreciating their works may we hope to bring the people back to reason and the right way.

Yet even among the hierarchy of examiners we do find that they occasionally confess to doubt and misgiving as to the efficacy of the system they are required to administer. Professor de Morgan declared that he could judge the candidate's capabilities by a brief personal inspection of his ordinary work far better than by examining papers representing the work of a whole week. If professional examiners spoke their mind, most of them would probably say the same thing. The real test of working capacity is left to be made by the employers later on. This is a fact which we commend to the notice of all such employers of technical labour. If they take note of it they will not attach too much value to examination certificates, nor too little to otherwise elegible persons who do not possess them. In due time, if this maxim were kept in mind, there would be no need to warn students against attempting to enter any or every profession by feats of mental legerdemain. Their sterling qualities would be tested otherwise, and on the rational as well as practical lines indicated in the remark of the eminent man above referred to.

One result of these examinations falling into disrepute—or, rather, let us say of their being cleared of the superstitions in which they are surrounded—would be that teachers would then have a chance of becoming famous. This they might do, if they have the right metal in them, even now, by working in defiance of examinations. To a large extent the teaching function has been superseded by the cramming. The so-called modern teacher is a sort of juggler who, having mastered the mysteries of the oracles, is willing to impart the secret to others for a handsome consideration. There is, we are told, a good deal of money

Digitized by Google

to be earned by this kind of teaching, which may be fitly described as the art of making ignorance to look knowing. But there is not much fame and little honour to be got by it. Such talents would pay better, as talents were wont to pay, we imagine, if they were invested in the old-fashioned establishment. Some people predict that crammer will grow altogether too clever for examiner. We sincerely hope he may. He is as much of a true prophet as the magicians of the Royal household, though that is not saying much; and when he has beaten them with their own enchantments deliverance from bondage may be near at hand.

We are well aware that nothing we can say in condemnation of this system is likely to make an impression upon it—it must wear itself out, or become too intolerable to be borne. But there are, as we have already hinted, some practical considerations which teachers and examiners, as well as students and employers, would do well to bear in mind in the interests of all alike. We speak especially of electrical science teaching, and our remarks are suggested by certain examination papers which lately came under our notice. Some of the questions seemed to presuppose that the candidates had been trained with a view to becoming theoretical electricians, and the mathematical workings were consequently very stiff. This we contend is a complete mistake. The amount of mathematical knowledge required for practical electrical engineering is not very great. It is the practical part of the profession that students want to learn, and employers require them to master. We shall not be suspected of underrating mathematics or the study of theoretical electricity; but we do object to their occupying a prominent place in the examiners' papers. The time devoted by the teacher to qualify his pupils to answer such questions would be far more usefully employed in teaching the practical part of other branches of science, several of which are now seen to play an important part in electrical engineering. We hope to return to this subject on a future occasion.

A GUIDE TO PRACTICE IN THE SUBMARINE CABLE TESTING ROOM.

VIII.

We give in this number two figures showing the connections for taking the capacity test with two different arrangements, as proposed in our last issue. Referring to the particular subject considered in the closing remarks, it will be noticed that the shunt is represented in both figures as connected directly to the galvanometer coils. In the galvanometer as used in the testing room these terminals are at the base, and here the shunt leads would really be joined. They are not, however, always connected directly, but are sometimes brought up to other terminals, the latter being connected to the galvanometer by other leads. If a short circuit key were used for the instrument, the shunt leads would be joined to the two terminals of that key, and where the plug commutator is used, as in the figure, these leads might more suitably be brought to the terminals A and A′. As long as they are connected to two points, which are also joined to the terminals of the galvanometer coils, it does not matter whether they are kept there or taken directly to the galvanometer itself. It is merely a case of leads in two sections instead of one. Some galvanometers have shunts made specially for them, in which case they are coils of a certain resistance, each being a proportional part of the galvanometer's resistance. They are usually marked $\frac{1}{9}$, $\frac{1}{99}$, $\frac{1}{999}$; when thus arranged they shunt off respectively $\frac{1}{10}$, $\frac{1}{100}$, $\frac{1}{1000}$ of the current passing in the circuit from the galvanometer, the deflection being, therefore, multiplied by 10, 100, or 1,000, as the case may be. We do not stop to show how these values are ascertained. The text books explain the rules for calculating shunt power. When the shunt is an ordinary resistance box, of course any resistance can be chosen and utilised by unplugging as much as we require.

We proceed now to consider the test for capacity taken with the connections as represented in Fig. 16. We will first test the condenser, and thus get a value by which to determine the capacity of the cable. We are not going to test the capacity of the condenser. We know what that is, it is $\frac{1}{2}$ or $\frac{1}{3}$rd of a microfarad, as the case may be; but we are to see what that capacity will give us. In other words, how many divisions on the scale will that known quantity or accumulation of electricity compel the galvanometer to show by discharging it through the coils. Let the condenser be $\frac{1}{2}$ microfarad. We choose this value because it makes the test somewwhat simpler, and the $\frac{1}{2}$ is as commonly used as the $\frac{1}{3}$ microfarad. One of the poles is to be connected to earth by a piece of insulated wire. There are several terminals in different parts of the room, or several wires each of which is connected with some good "earth," generally a large copper plate, buried in a damp spot, which suffices for as many earth terminals as may be joined to it. Next, the other condenser pole will be joined up to the quadrant B of the four-way piece (Fig. 16), connection with which to the key is effected by the plugs and the short lead to L, and the plug in the battery commutator will be removed to the hole for joining 10 cells. Now, if we were to charge this condenser and then discharge it through the galvanometer without having any shunt in circuit we should cause the mirror to swing so far that the spot would pass far beyond the end of the scale—we should get no readable deflection. The answer to the question, "What resistance ought our shunt to have?" depends on the resist-

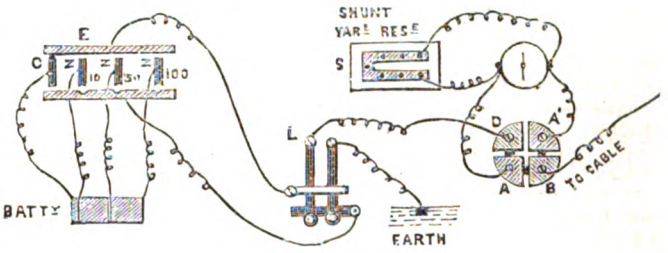

FIG. 16.

ance of the galvanometer used. The learner would most likely be saved all difficulty on this point, since he would be told what shunt to use, it being usual to note the amount of resistance necessary for the galvanometer which is to be employed (that is, with reference to the condenser). Supposing, however, that he were obliged to find it out for himself, it may be useful presently to show him how to set about it. For the moment we must point out how the discharge is effected. The operator will see that no charge can come from the battery as long as the key pieces L and L′ are up against the bar, because one pole is to earth and the other is insulated, but when (after removing the condenser plug) the left hand key L is pressed down (Fig. 16) a charge will pass out at L through D and by A and B to the condenser (which is supposed to be in the place of the cable in the figure), and if the plug remained inserted between A and B, the galvanometer, as before shown, would be short circuited, the charge going straight across to the condenser. Leaving this so for the moment, let us suppose we suddenly release the key, which we had kept pressed down; it will fly up against the upper bar and the charge will rush back from the condenser and pass to earth by coming back to L and by this bar to the terminal connected to earth, taking exactly the reverse of the course followed in charging. The condenser has been discharged, but there is no deflection on the scale. Of course, in practice no one would purposely bring this about, but if it were done, say, by accident, it would be proper to insert the condenser plug for a moment to cause any residual charge in the one side to be dissipated or destroyed by recombination with the opposite kind of electricity in the other side. The galvanometer short-circuit plug must necessarily be removed to allow of a deflection, and then when the

Digitized by Google

key is sprung back the discharge goes by A^1 through the galvanometer, and shunt if any, to A, and finally to earth by the key. When a shunt is used, as stated to be necessary, it acts as a branch circuit, and if judiciously chosen, gives a good deflection. After noting the value (the number of divisions passed over by the spot), the condenser will be removed, and the cable joined up in its place. This may be done by plugging in the large commutator described in No. I., and thus connecting one end of either the core or cable lead to a terminal near the instrument, which terminal has a short lead to the small galvanometer commutator; or, if there should be no large commutator, there will be a lead to which the cable would be joined, and the end of this may be connected to the terminal. In effect, the arrangement is practically as shown in Fig. 16. Remembering that it was necessary to put one pole of the condenser to earth for testing, the learner may not, perhaps, see how to satisfy the condition in the case of the cable. But a moment's consideration of some foregoing remarks in No. VI. will remind him that the cable has always one pole to earth through its outer sheathing, though it is only when concerned with electricity in a *static* form, or, as an accumulated charge, that we regard it as having opposite poles. With *current* electricity the copper interior is simply a conductor, or may be so considered. At any rate the two cases may be looked at as practically distinct.

Continuing the test, supposing the shunt to have been properly chosen, and its required resistance unplugged in the shunt box, the left-hand key will be pressed down as before, and, after 15 seconds or so, the short circuit plug between A and B (Fig. 16) will be taken out, and, 15 seconds later, the key will be suddenly released, the operator keeping his eye on the scale and marking the number of the division at which the spot stops before flying back, which, of course, it must do since the discharge had caused it to swing from its position of rest to which it naturally returns. This deflection being noted, the determination of the cable's capacity is easy enough. As a discharge from a condenser of $\frac{1}{2}$ microfarad capacity with a shunt of a certain resistance is found to be so many divisions, say 350, what is the capacity of a cable (also a condenser) whose discharge with a certain shunt gives us 340 divisions? Or, in rule of three shape:—As 350 × the multiplying power of the shunt : 340 × the multiplying power of *its* shunt :: $\frac{1}{2}$ microfarad : the number of $\frac{1}{2}$ microfarads of the cables; and as the condenser is $\frac{1}{2}$ microfarad, or m.f.d., one m.f.d. would have given twice the deflection, therefore the question may be put thus:—As twice the condenser's deflection value : to that of the cable :: 1 m.f.d. to the capacity of the latter.

A word or two about the choice of a shunt is appropriate at this point; the learner will find it of assistance in such a case as where he has no idea what resistance he ought to use, and no information by comparison with other cables or condensers. The spot of light is, let us say, in the centre of the scale at zero. The discharge being measured by the swing, and the object being to compare the one deflection with the other, it is advisable to have as large a deflection as possible within the limits of the scale. It must be noted that the spot flies over the divisions pretty sharply, and practice is required to mark correctly the line representing the true deflection. The beginner seeking to find the proper shunt should begin with trying a very small one, the smaller the better; for he will understand that the smaller the resistance of the shunt is the greater is the proportion of the charge shunted off from the galvanometer, and that which passes through the galvanometer coils is alone concerned in producing the deflection. Finding, after charging and discharging with the shunt he tried as a first attempt, that the deflection is too small, he should unplug more resistance and try again until he finds the discharge gives him, say, 350. It is proper to insert the condenser plug for a moment after each operation, for the reason given above, namely, that its plates may be thoroughly discharged.

It will be seen that when, in the course of the test, the short circuit plug is taken out from between A and B the *charge* which went straight to the cable now goes also through the galvanometer, but no deflection is caused until the *discharge* takes place, and this may appear strange. If the learner did not take notice of this just now, the point would most probably occur to him later on, and the explanation is appropriate to the immediate subject. A glance at the connections in Fig. 16 will, in the first place, show that the deflection (say to the *right* on the scale) is caused by the discharge from the cable going through A′ and round the galvanometer coils, whilst the *charge* goes by A in the opposite direction, so that any deflection from the latter could only be on the *left* side of the scale; but even on this side no deflection is seen. A second point to be noticed is that a small battery power only is employed, and then the shunt relieves the galvanometer of so great a portion of the charge which would otherwise pass through it that the impulse in this direction is practically reduced to *nil*.

We will now take this test with the connections as seen in Fig. 17. It is to be observed that the shaded part in the trigger key is intended to represent *conducting* portion, and that left white is insulating. Here the galvanometer has no concern with the *charge*, but is simply affected by the *discharge*. It would be simpler in some respects to dispense with the galvanometer commutator or four-way piece, but then we could not bring the deflection at will on either side of the scale when using the same current. With the commutator as here shown we can reverse the deflection, bringing it either to the right or left. Further, we can make the opposite currents deflect the mirror always on the same side by merely shifting the plugs; and this is often necessary, as when we wish to see if a positive current gives the same discharge as a negative current. For though this might be done by observing the deflections on both sides of the centre or zero, it is better to have both on the same side,

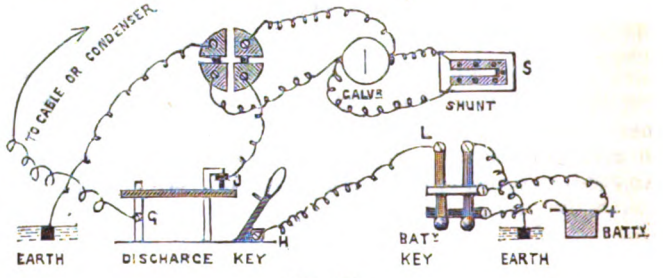

Fig. 17.

since the suspension of the mirror may cause a current to show a trifling difference in the swing on opposite sides. The spot might give 300 when swinging to the right, and 298, perhaps, if swung to the left.

The condenser will first be joined up, as it was in the other case (10 cells being plugged in the battery commutator); the leads from the battery are in the figure taken directly to the key, but the commutator is supposed to intervene. The battery key will be depressed and clamped down. This may remain so until the test is finished, because no charge will result until the trigger key connects it with the condenser or cable. This latter key (that is, the handle) is now to be pushed on to the bar, which is thus pressed down a little and disconnected from the point J. The charge enters the condenser, and after, say 20 or 30 seconds, the trigger is drawn back and the bar, striking against J, causes the discharge from the condenser to pass through the galvanometer and shunt, and by the commutator to earth. The deflection is noted, and the cable substituted for the condenser, and the same process is repeated with it. The battery key should always be carefully released after the test. It should never be left down when not in use.

This test for capacity by discharge is for general purposes sufficiently correct, and very handy in relation to its simplicity, but it does not give absolutely true results; and further on we shall explain the reasons for preferring the test by balance which will come before us in a later number.

The learner will remember the actual state of arrangement of the cable and core as described in an early paper, and shown in No. V., Fig. 9. He will see that both core and cable end is insulated at the large commutator, as long as no plug connects the bar to anything else, and though in the

Digitized by Google

figure the connections are for the electrometer, there are other bars crossing the core and cable bars, and by plugging in at the proper place connection would be made for the discharge test instead of the electrometer. He could, therefore, test for capacity from either end by plugging in at the bar to which the core lead is joined, and leaving the opposite or cable bar free, or *vice versâ*. The discharge should be exactly the same either way.

We now take leave of this test for the present, and shall turn to the interesting subject of insulation resistance, and how it is measured.

STUDENTS' COLUMNS.

A small space will be devoted to the discussion of examinations, and examination questions. We think students should send us specimen solutions to the various examination questions, that we might select such answers for publication as seemed to us to come nearest to the answer required by the examiners. There are certain classes of questions which we cannot discuss, except in the manner indicated. We cannot in these columns undertake to describe or compare machines, though we might give John Brown's answer to such a question. We cannot select one machine for description out of a dozen. Answers requiring this must be the work of individual readers, and not ours. Certain questions are set by examiners with a special object, such, for example, as to test the observing powers of the candidate, or his generalising power. It may interest a few to have answers to such questions—to us it would mean a waste of space, and confer no real benefit whatever. Many of the answers will be framed more to give information than to give a specimen answer. We do not seek to aid a certain few men to pass an examination, but to aid the many students to give a definiteness and concreteness to their knowledge. Answer questions, not to pass examinations, but to be sure you know the subject, not resting satisfied with the mere idea that you know it:—

City and Guilds Institute.

Examination Papers, 1882.

1. Explain fully why at the present day it is more economical to light large rooms with the electric light than with gas, and why this was not the case some few years back?

Ans. A few years ago (1) the current required for electric lamps had to be obtained by the consumption of zinc in the ordinary voltaic batteries. The cost from this alone rendered the electric light far less economical than that of gas; (2) the electric lamps were more cumbrous—and almost entirely of the "arc" type—than similar lamps of the present day; (3) the discovery of Faraday, which led to the invention of magneto and dynamo machines, has also led to an immense cheapening of the electric current required for electric lamps, hence the improvements in lamps and machines enable us now to compete successfully with gas in lighting large rooms, and especially so where using "arc" lamps.

2. What is the principle of a dynamo machine? Explain in detail the construction of the dynamo with which you are best acquainted, describing the nature of the material (soft iron, cast iron, or steel, &c.) employed in each part, and giving full sketches illustrating the mode of winding the coils, and the size and shape of each part of the machine, as well as the reasons, as far as you know them, for the method of manufacture employed.

Ans. Induction. Professor Adams (Cantor Lectures) says:—"The fundamental principles which underlie all magneto-electric machines are the four great principles discovered by Oersted in 1819, by Ampère and Arago in 1820, and by Faraday in 1831. In 1819, Oersted discovered the action of a current of electricity on a magnet. In 1820, Ampère discovered the action of magnets and currents on currents of electricity in their neighbourhood, and in the same year Arago showed that currents of electricity produced magnetisation, thus laying the foundation of electromagetism; and in 1831 Faraday showed that induced currents were produced by the motion of magnets. All machines for the conversion of work into electricity are founded on Faraday's great discovery of the induced current, derived from the relative motion of a magnet and a coil of wire."

[The answer to the latter portion of this question we cannot give, inasmuch as we must, by giving it, necessarily describe some particular machine, and, however unbiased we might be, many would regard such description as showing we had a leaning in favour of some one machine, which would be an inference altogether at variance with the true state of the case, which is that we view all machines in the same light, and have no preference.—Ed. *E.*]

3. Explain fully, with sketches, how dynamo machines of the Brush type differ from those of the Gramme. What are the relative advantages and disadvantages of direct and alternate current dynamos?

Ans. The answer to the first part of this question can be obtained by consulting any modern book on electric lighting, such as those of Dredge, Higgs, Hospitalier. With direct current machines, almost any lamp (arc or incandescent) may be used, secondary batteries may be charged, power transmitted, and a second machine is not generally used as an exciter. It has the disadvantage of requiring brushes, and hence more and more loss with currents of great intensity. With alternate current machines an exciter is generally used. These machines can be employed with only certain arc lamps, but incandescent lamps are *said* to have a longer life when they are used. Alternate current machines are not adapted for transmitting power, nor charging secondary batteries, nor for many electro-chemical and metallurgical operations. They have the advantage that any number of the coils may be connected in series, or in multiple arc. Each set of coils may be connected to an external circuit. There seems to be no limit to the intensity of current which may be obtained except such as is imposed by the properties of the materials used in construction. Alternate current machines are more liable to loss by heat developed where it is not wanted than are direct current machines, &c.

[We must say that the word "relative" in the question renders it quite incomprehensible to us, and the above must therefore be taken for what it is worth.]

5. How many feet (about) of copper wire $\frac{1}{20}$th of an inch in diameter would have one ohm resistance at 60°F.? About how much per cent. is the resistance of copper wire altered by an increase of 15°F. in the temperature, and is the resistance increased or decreased?

Ans. About 230 or 240 feet.

If the student is to show how the number of feet is obtained he may work thus:—

1 mile (1,760 yards) copper wire has $R = \frac{54892}{d^2}$, where d is expressed in mils., *i.e.*, $\frac{1}{1000}$th of an inch.

Now $\frac{1}{20}$ inch = 50 mils.

∴ Resistance of 1 mile of wire 50 mils. in diameter is found

$$R = \frac{54892}{(50)^2} = \frac{54892}{2500} = \frac{219568}{10000} = 21{\cdot}9568.$$

$$\therefore \frac{1760 \times 3}{21{\cdot}9568} = \text{number of feet per ohm} = 240 \text{ nearly.}$$

or

As the percentage increase resistance of Cu. wire per 1°F. is about ·21, say ·2, and 1 foot of hard-drawn Cu. wire 1 mil. diameter at 32°F. has R = 9·940 ohms—say, for simplicity, = 10 ohms,

∴ The number (x) feet of Cu. wire in 1 ohm of 50 mils. diameter

$$= \frac{10 \times x}{2500} = 1.$$

$x = 250$ = number of feet with R = 1 ohm at 32°F.,

60°F. − 32°F. = 28°F.,

and $28 \times {\cdot}2 = 5{\cdot}6$, which represents increased resistance per cent. for the 28°.

$$\therefore 250 - (2{\cdot}5)\,(5{\cdot}6) = R \text{ at } 60° = 250 - 14 = 236.$$

The resistance increases ·21 per cent. for a rise of temperature of 1°F.

INTERNATIONAL CONFERENCE FOR THE PROTECTION OF SUBMARINE CABLES.

Introductory report, drawn up by the special committee, composed of MM. Dambach (Germany), Renault (France), Trevor (Great Britain), Velasco (Mexico),* Asser (Netherlands).

Before commenting briefly on the various proposals we submit for discussion to the Conference, we deem it right to state that our resolutions do not commit the Governments of the delegates present, but are intended only to facilitate the deliberations of the Conference. The general scope of our proposals may be thus summed up. We have endeavoured to show our utmost respect for the sovereignty and laws of the contracting States, and have suggested only such fresh enactments as appeared to us indispensable for the attainment of the desired end.

The high contracting parties being desirous of securing the maintenance of telegraphic communications by means of submarine cables have agreed on a convention to this effect, and have appointed:—

Clause I. "The present Convention applies outside territorial waters to all submarine cables legally laid between the territories of the high contracting parties."

The Convention applies only to cases outside territorial waters, for its object is precisely to regulate the common use of the high sea, which is the domain of no particular State. As for what occurs on the territory, or within the territorial waters, of any particular State, it is for that State to bring such case within the ambit of its regular sovereignty. As a rule submarine cables are protected by the existing laws of the various States against all interference at their landing stages, or within territorial waters. If by chance this were not the case in any State desirous of joining the Convention such State must, of course, make the necessary enactments; for, of course, one cannot understand an act being punishable if committed on the high seas, and yet unpunishable if committed on the territory, or within the territorial waters of such a State.

By the expression "all cables legally laid," we have desired to point out that there was no distinction to be drawn between State and private cables, that it was sufficient for them to have been regularly established.

But we have only in view the cables connecting contracting States, for this Convention is intended to benefit only those States who are signatories thereto, and not those States unwilling to incur the obligations it imposes on Governments and individuals.

Clause II. "The breaking or deteriorating of a submarine cable, when done wilfully or through culpable negligence, and having for result the interruption or impeding of telegraphic communication, is punishable, without prejudice to a civil action for damages."

This provision does not apply to breakages or deteriorations effected with the sole object of protecting life, or of securing the safety of a vessel, and after taking all necessary precautions for avoiding such breakages or deteriorations.

Paragraph first of this clause is worded in accordance with general usage in this respect. It has for its object two different sets of circumstances. The damage may have been done with even *malicious* intent, for the purpose of interrupting the telegraphic communication from some interested motive or other. This is the simplest case of all, and should admit of no hesitation, since the act concerned is both pernicious and prejudicial.

On the other hand, it may happen that the damage has not been perpetrated in the spirit suggested above, but is the result merely of negligence. Thus, an anchor or trawl may foul a cable. Well, with a little care, or, as an English judgment has it, "with ordinary seafaring skill," the anchor or trawl might be got clear without damaging the cable; whereas, on the contrary, the fishermen or sailors take no such precautions, but go roughly to work, and by their carelessness either break or injure the cable. Such negligence should therefore be punished.

We have deemed it best to confine ourselves to this general rule, and to leave it to the judges to determine in each case whether there has been culpable negligence, or whether, to borrow the words of an important official document (*vide* Article 247 of Décret Français, 4th November, 1879, concerning rules for preventing collisions at sea), "the precautions enjoined by ordinary seafaring experience, and the particular circumstances under which the vessel was at the time, have been complied with."

Strictly speaking, this clause might have been limited to its first paragraph. For, of course, if the master of a ship or smack cuts or damages a cable solely for the purpose of saving his life or his craft, he cannot be held to have been guilty of fraudulent intent or culpable negligence. With a view, however, of precluding all misunderstanding and equivocation on this head, as also of preventing a scare amongst seafaring men from the general terms of the first paragraph, we have deemed it needful to use extra explicitness, and tack on this outrider.

Clause III. "The high contracting parties hereto mutually undertake to prevent as much as possible the various submarine cables from crossing one another, or being in too close proximity to one another."

The idea conveyed in this clause was adopted by the Conference in its fifth sitting (*vide* Minutes, page 17). The committee has only applied itself to the elimination of such terms as had given rise to disagreements, notably the word "juxtaposé," and they venture to hope the wording they have adopted will satisfy the wishes of the Conference.

The proposed clause expresses a general undertaking on the part of the several Governments without specifying the means for carrying it out, the said Governments being thus at liberty to dictate their terms to the parties soliciting concessions without troubling themselves about what course of action the Government at the other end of the cable may think fit to pursue, or, on the contrary, to come to an understanding with him.

Clause IV. "The owner of a cable which, when being laid or repaired, breaks or injures another cable, shall bear the cost of the repairs necessitated by such breakage or injury, without prejudice, if occasion calls for it, of Clause II."

The principle embodied in this clause was recognised by the Conference in its fifth sitting (*vide* Minutes, page 17).

The concluding words of this Clause IV. are intended to show that the obligation of indemnification is based on the material injury done, and not on the indirect injury resulting from the interruption of telegraphic communication.

Clause V. "The vessels employed in the laying or repairing of submarine cables must observe the rules as to signals which are or shall be adopted in common accord by the high contracting parties with a view to prevent collisions.

"When a vessel engaged in repairing a cable has thus signalled, the other ships and craft which see or can see said signals must either draw off, or keep at a distance of at least one nautical mile from said vessel, so as not to bore her in her movements.

"Fishing boats must keep their nets and fishing gear the same distance away from said repairing vessel.

"All ships or craft when thus signalled by said repairing ship shall have a delay of twenty-four hours at the outside accorded them, during which term no obstacle shall be placed in the way of their movements.

"The telegraph repairing vessel shall complete its operations with all possible celerity."

This clause was drafted in consonance with the information supplied by the technical delegates. We have, in the wording of its stipulations, endeavoured to conciliate the interests of the telegraph repairing ships with those of other ships, and specially of fisher boats.

It was generally agreed that it was not necessary to insist on any special regulations for the guidance of ships engaged in laying cables, but that such regulations were necessary for the guidance of ships which, engaged in repairing broken or injured cables, are compelled to remain more or less in the one spot, and have not the choice of weather for doing their work. It is, therefore, to the general interest that they shall not be interfered with in their work, so that they may get through it with all possible celerity, and that telegraphic communications may be restored. It is equally to the interest of the cable owners themselves that the repairs be promptly executed, and this interest is in itself a guarantee that the inconvenience thus occasioned to merchant ships or fisher boats will not be continued longer than necessary.

Clause VI. "All craft seeing, or capable of seeing, the buoys used for indicating the position of cables shifted or broken shall keep at a quarter of a mile off at least.

"Fishermen shall keep their nets and fishing gear and appliances at an equal distance."

Article VII. "The owners of ship or craft able to prove they have sacrificed an anchor or net so as not to damage a submarine cable shall be indemnified by the owner of said cable.

"In order to be able to lay claim to such indemnity, a detailed report must be drawn up of the accident, as soon after its occurrence as possible, and attested by the crew. At at events the master of the vessel concerned must always, within twenty-four hours after reaching port of destination or call, lodge his declaration with the officials concerned. These officials shall notify the fact to the consuls or consular agents of the country to which the owner of the cable belongs."

Clause VIII. "The tribunals competent to take cognizance of infractions of this Convention are those of the nation to which the delinquent ship or craft belongs, subject to the subsidiary application of the general rules of national penal competency springing out of the particular laws of States or international treaties."

The essential provision of this clause seems to be qualified in the first place by the general principles of penal law, according to which the tribunal naturally competent to try an infraction is the tribunal of the country wherein the infraction has been committed. On the high seas vessels may be considered as forming part of the territory of the State whose flag they fly. It is, therefore, consonant with logic that the tribunals of such State should adjudicate on the infractions committed on board such vessels, whatever may be the nationality of the delinquents themselves.

This stipulation is specially commendable from the fact of its being analogous to one contained in the Hague Fishery Convention (Clause 36). A member of the committee, however, has suggested drafting the opening of the clause thus:—

"The tribunals competent to take cognizance of infractions of this Convention are those of the State the least removed from the spot where the delinquency was committed."

We will now proceed to explain the meaning of the proviso at the end of this eighth clause. It alludes to the particular laws of States and to international treaties, and calls for a word of explanation on these two points.

1. It may happen that the tribunals of a State which are not competent according to the preceding rule may be so by virtue of another principle. Let us, then, suppose a German or Frenchman committing such an infraction of the Convention on board a British vessel. If tried by the British Court there is an end of the matter. But this German or Frenchman may return to his own country without having been tried in England. Is he, or are they, to evade all punishment because his or their native country will not surrender him or them to England? This is unnecessary, and there is no reason for discarding the application of common law, which allows a State to demand an account of its subjects of their doings abroad. The Frenchman or the German can be prosecuted in their own country, by virtue of common law (German Penal Code, Clause ——; French Penal Code, Clause 5). This provision should, therefore, meet with the concurrence of all the Powers, for it is for the benefit of their sovereignty.

2. According to certain treaties, the subjects of one State are exempted from the jurisdiction of another State, as subject only to the jurisdiction of their own country. The principle laid down in the opening of the clause if applied singly would lead to inadmissible results.

Clause IX. "The prosecution for delinquencies and contraventions described in this Convention shall be conducted in the name of or by the State."

This is a reiteration of Clause 34 of the Hague Fishery Convention.

Mr. Trevor, however, has recorded certain provisos on this point.

Clause X. "The infraction of this Convention can be verified by all modes of proof permitted by the laws of the country wherein the Court appealed to sits. Moreover, the commanding officers of men of war, or of vessels specially commissioned for such purpose by one of the high contracting parties, whatever be the nationality of the craft whereon the infraction has been committed, may report on the proceedings.

"These reports shall be drawn up in accordance with the formalities, and in the language in use in the country to which the officer thus reporting

* Unforeseen circumstances having necessitated Mr. Asser's recall from Paris, his place during several sittings was taken by Mr. Jansen.

Digitized by Google

belongs, and shall have the same weight in the country they may be appealed to as if they emanated from the competent authorities of that country."

For the proof of the infractions, the clause refers to the laws of the country wherein they are tried, that is the common law.

The right of reporting was adopted by analogy by the Hague Fishery Convention (Clause 28).

The second paragraph is a reiteration of Clause XXXI., Paragraph I., of the same Convention.

Clause II. "The procedure and the judgment of the contraventions of the provisions of this Convention shall always be carried out as summarily as the laws and regulations in force permit."

This clause is only a reiteration of Clause 37 of the Hague Fishery Convention.

Article XII. "The high contracting parties hereto undertake to adopt, or to propose to their respective Legislatures, the measures requisite for carrying out this Convention, and notably for punishing either with imprisonment or fine, or both, all contraventions of the provisions of Clauses 2, 5, and 6."

Clause XIII. "The high contracting parties hereto shall communicate the laws which may already have been passed, or may subsequently be passed, in their respective States relative to the object of this Convention."

Clause XIV. "This Convention shall be ratified. The ratification shall be interchanged in Paris within the shortest delay possible."

Clause XV. "This Convention shall be in force from the day the high contracting parties shall agree on.

"It shall remain in force —— years from said date, and in the event of any of the high contracting parties failing to notify twelve months before the expiration of said term of —— years its intention of withdrawing from this Convention, it shall continue in force another year, and so on from year to year.

"In the event of any of the high contracting parties renouncing this Convention, such renunciation would affect only the high contracting party thus renouncing."

SOCIETY OF ARTS.

On Wednesday, Nov. 15, the President, Dr. C. W. Siemens, F.R.S., gave his inaugural address, which referred principally to electric lighting. Dr. Siemens said: Having received the honour of being elected Chairman of the Council of the Society of Arts for the ensuing year, the duty devolves upon me of opening the coming session with some introductory remarks.

* * * * *

Amongst the practical questions that now chiefly occupy public attention are those of electric lighting, and of the transmission of force by electricity. These together form a subject which has occupied my attention and that of my brothers for a great number of years, and upon which I may consequently be expected to dwell on the present occasion, considering that at Southampton I could deal only with some purely scientific considerations involved in this important subject. I need hardly remind you that electric lighting, viewed as a physical experiment, has been known to us since the early part of the present century, and that many attempts have from time to time been made to promote its application. Two principal difficulties have stood in the way of its practical introduction, viz., the great cost of producing an electric current so long as chemical means had to be resorted to, and the mechanical difficulty of constructing electric lamps capable of sustaining with steadiness prolonged effects. The dynamo-machine, which enables us to convert mechanical into electrical force, purely and simply, has very effectually disposed of the former difficulty, inasmuch as a properly conceived and well constructed machine of this character converts more than 90 per cent. of the mechanical force imparted to it into electricity, 90 per cent. again of which may be re-converted into mechanical force at a moderate distance. The margin of loss, therefore, does not exceed 20 per cent., excluding purely mechanical losses, and this is quite capable of being further reduced to some extent by improved modes of construction; but it results from these figures that no great step in advance can be looked for in this direction. The dynamo-machine presents the great advantage of simplicity over steam or other power-transmitting engines; it has but one working part, namely, a shaft which, revolving in a pair of bearings, carries a coil or coils of wire admitting of perfect balancing. Frictional resistance is thus reduced to an absolute minimum, and no allowance has to be made for loss by condensation, or badly fitting pistons, stuffing boxes, or valves, or for the jerking action due to oscillating weights. The materials composing the machine, namely, soft iron and copper wire, undergo no deterioration or change by continuous working, and the depreciation of value is therefore a minimum, except where currents of exceptionally high potential are used, which appear to render the copper wire brittle. The essential points to be attended to in the conception of the dynamo-machine are the prevention of induced currents in the iron, and the placing of the wire in such position as to make the whole of it effective for the production of outward current. These principles, which have been clearly established by the labours of comparatively few workers in applied science, admit of being carried out in an almost infinite variety of constructive forms, for each of which may be claimed some real or imaginary merits regarding questions of convenience or cost of production. For many years after the principles involved in the construction of dynamo-machines had been made known, little general interest was manifested in their favour, and few were the forms of construction offered for public use. The essential features involved in the dynamo-machine, the Siemens armature (1856), the Pacinotti ring (1861), and the self-exciting principle (1867), were published by their authors for the pure scientific interest attached to them, without being made subject matter of letters patent, which circumstance appears to have had the contrary effect of what might have been expected, in that it has retarded the introduction of this class of electrical machine, because no person or firm had a sufficient commercial interest to undertake the large expenditure which must necessarily be incurred in reducing a first conception into a practical shape. Great credit is due to Monsieur Gramme for taking the initiative in the practical introduction of dynamo-machines embodying those principles, but when, five years ago, I ventured to predict for the dynamo-electric current a great practical future, as a means of transmitting power to a distance, those views were still looked upon as more or less chimerical. A few striking examples of what could be practically effected by the dynamo-electric current, such as the illumination of the Place de l'Opera, Paris, the occasional exhibition of powerful arc lights, and their adoption for military and lighthouse purposes, but especially the gradual accomplishment of the much desired lamp by incandescence in vacuum, gave rise to a somewhat sudden reversion of public feeling; and you may remember the scare at the Stock Exchange, affecting the value of gas shares, which ensued in 1878, when the accomplishment of the sub-division of the electric light by incandescent wire was first announced, somewhat prematurely, through the Atlantic cable.

From this time forward electric lighting has been attracting more and more public attention, until the brilliant displays at the exhibition of Paris, and at the Crystal Palace last year, served to excite public interest to an extraordinary degree. New companies for the purpose of introducing electric light and power have been announced almost daily whose claims to public attention as investments were based in some cases upon only very slight modifications of well-known forms of dynamo-machines, of arc regulators, or of incandescent carbon lights, the merits of which rested rather upon anticipations than upon any scientific or practical proof. These arrangements were supposed to be of such superlative merit that gas and other illuminants must soon be matters simply of history, and hence arose great speculative excitement. It should be borne in mind, however, that any great technical advance is necessarily the work of time and serious labour, and that when accomplished, it is generally found that so far from injuring existing industries, it calls additional ones into existence, to supply new demands, and thus gives rise to an increase in the sum total of our resources. It is, therefore, reasonable to expect that side by side with the introduction of the new illuminant, gas lighting will go on improving and extending, although the advantages of electric light for many applications, such as the lighting of public halls and warehouses, of our drawing rooms and dining rooms, our passenger steamers, our docks and harbours, are so evident, that its advent may be looked upon as a matter of certainty. Our legislature has not been slow in recognising the importance of the new illuminant. In 1879 a Select Committee of the House of Commons instituted a careful inquiry into its nature and probable cost, with a view to legislation, and the conclusions at which they arrived were, I consider, the best that could have been laid down. They advised that applications should be encouraged tentatively by the granting of permissive Bills, and this policy has given rise to the Electric Lighting Bill, 1882, promoted by Mr. Chamberlain, the President of the Board of Trade, regarding which much controversy has arisen. It could, indeed, hardly be expected that any act of legislation upon this subject could give universal satisfaction, because while there are many believers in gas who would gladly oppose any measure likely to favour the progress of the rival illuminant, and others who wish to see it monopolised, either by local authorities or by large financial corporations, there are others again who would throw the doors open so as to enable almost all comers to interfere with the public thoroughfares, for the establishment of conducting wires, without public let or hindrance. The law as now established takes, I consider, a medium course between these diverging opinions, and, if properly interpreted, will protect, I believe, all legitimate interests, without impeding the healthy growth of establishments for the distribution of electric energy for lighting and for the transmission of power. Any firm or lighting company may, by application to the local authorities, obtain leave to place electric conductors below public thoroughfares, subject to such conditions as may be mutually agreed upon, the term of such license being limited to seven years; or an application may be made to the Board of Trade for a provisional order to the same effect, which, when sanctioned by Parliament, secures a right of occupation for twenty-one years. The license offers the advantage of cheapness, and may be regarded as a purely tentative measure, to enable the firm or company to prove the value of their plant. If this is fairly established, the license would in all probability be affirmed, either by an engagement for its prolongation from time to time, or by a provisional order which would, in that case, be obtained by joint application of the contractor and the local authority. At the time of expiration of the provisional order, pre-emption of purchase is accorded to the local authority, against which it has been objected with much force by so competent an authority as Sir Frederick Bramwell that the conditions of purchase laid down are not such as fairly to remunerate the contracting companies for their expenditure and risk, and that the power of purchase would inevitably induce the parochial bodies to become mere trading associations. But while admitting the undesirability of such a consummation, I cannot help thinking that it was necessary to put some term to contracts entered into with speculative bodies at a time when the true value of electric energy, and the best conditions under which it should be applied, are still very imperfectly understood. The supply of electric energy, particularly in its application to transmission of power, is a matter simply of commercial demand and supply, which need not partake of the character of a large monopoly similar to gas and water supply, and which may therefore be safely left in the hands of individuals, or of local associations, subject to a certain control for the protection of public interests. At the termination of the period of the provisional order, the contract may be renewed upon such terms and conditions as may at that time appear just and reasonable to Parliament, under whose authority the Board of Trade will be empowered to effect such renewal. Complaints appear almost daily in the public papers to the effect that townships refuse their assent to applications by electric light companies for provisional orders; but it may be surmised that many of these applications are of a more or less speculative character, the object being to secure monopolies for eventual use or sale, under which circumstances the authorities are clearly justified in withholding their assent, and no licenses or provisional orders should, indeed, be granted, I consider, unless the applicants can give assurance of being able and willing to carry out the work within a reasonable time. But there are technical questions involved which are not yet sufficiently well understood to admit of immediate operations upon a large scale. Attention has been very properly called to the great divergence in the opinions expressed by scientific men regarding the area that each lighting district should comprise, the capital required to light such an area, and the amount of electric tension that should be allowed in the conductors. In the case of gas supply the works are necessarily situated in the

Digitized by Google

outskirts of the town, on account of the nuisance this manufacture occasions to the immediate neighbourhood: and, therefore, gas supply must range over a large area. It would be possible, no doubt, to deal with electricity on a similar basis, to establish electrical mains in the shape of copper rods of great thickness, with branches diverging from them in all directions; but the question to be considered is, whether such an imitative course is desirable on account either of relative expense or of facility of working. My own opinion, based upon considerable practical experience and thought devoted to the subject, is decidedly adverse to such a plan. In my evidence before the Parliamentary Committee I limited the desirable area of an electric district in densely populated towns to a quarter of a square mile, and estimated the cost of the necessary establishment of engines, dynamo machines, and conductors at £100,000, while other witnesses held that areas from one to four square miles could be worked advantageously from one centre, and at a cost not exceeding materially the figure I had given. These discrepancies do not necessarily imply wide differences in the estimated cost of each machine or electric light, inasmuch as such estimates are necessarily based upon various assumptions regarding the number of houses and of public buildings comprised in such a district, and the amount of light to be apportioned to each, but I still maintain my preference for small districts. By way of illustration, let us take the parish of St. James's, near at hand, a district not more densely populated than other equal areas within the metropolis, although comprising, perhaps, a greater number of public buildings. Its population, according to the preliminary report of the census taken on the 4th April, 1881, was 29,865, it contains 3,018 inhabited houses, and its area is 784,000 square yards, or slightly above a quarter of a square mile. To light a comfortable house of moderate dimensions in all its parts, to the exclusion of gas, oil, or candles, would require about 100 incandescent lights of from 15 to 18 candle-power each, that being, for instance, the number of Swan lights employed by Sir William Thomson in lighting his house at Glasgow University. Eleven horse-power would be required to excite this number of incandescence lights, and at this rate the parish of St. James's would require 3,018 × 11 = 33,200 horse-power to work it. It may be fairly objected, however, that there are many houses in the parish much below the standard here referred to, but, on the other hand, there are 600 of them with shops on the ground floor, involving larger requirements. Nor does this estimate provide for the large consumption of electric energy that would take place in lighting the 11 churches, 18 club houses, 9 concert halls, 3 theatres, besides numerous hotels, restaurants, and lecture halls. A theatre of moderate dimensions, such as the Savoy Theatre, has been proved by experience to require 1,200 incandescence lights, representing an expenditure of 133 horse-power; and about one-half that power would have to be set aside for each of the other public buildings here mentioned, constituting an agregate of 2,926 horse-power; nor does this general estimate comprise street lighting, and to light the six and a-half miles of principal streets of the parish with electric light would require, per mile, 35 arc lights of 350 candle-power each, or a total of 227 lights. This, taken at the rate of 0·8 horse-power per light, represents a further requirement of 182 horse-power, making a total of 3,108 horse-power, for purposes independent of house lighting, being equivalent to one horse-power per inhabited house, and bringing the total requirements up to 109 lights = 12 horse-power per house. I do not, however, agree with those who expect that gas lighting will be entirely superseded, but have, on the contrary, always maintained that the electric light, while possessing great and peculiar advantages for lighting our principal rooms, halls, warehouses, &c., owing to its brilliancy, and more particularly to its non-interference with the healthful condition of the atmosphere, will leave ample room for the development of the former, which is susceptible of great improvement, and is likely to hold its own for the ordinary lighting up of our streets and dwellings. Assuming, therefore, that the bulk of domestic lighting remains to the gas companies, and that the electric light is introduced into private houses, only at the rate of, say, 12 incandescence lights per house, the parish of St. James's would have to be provided with electric energy sufficient to work (9 + 12) 3,018 = 63,378 lights = 7,042 horse-power effective; this is equal to about one-fourth the total lighting power required, taking into account that the total number of lights that have to be provided for a house are not all used at one and the same time. No allowance is made in this estimate for the transmission of power, which, in course of time, will form a very large application of electric energy; but considering that power will be required mostly in the day time, when light is not needed, a material increase in plant will not be necessary for that purpose.

In order to minimise the length and thickness of the electric conductor, it would be important to establish the source of power, as nearly as may be, in the centre of the parish, and the position that suggests itself to my mind is that of Golden-square. If the unoccupied area of this square, representing 2,500 square yards, was excavated to a depth of 25 feet, and then arched over so as to re-establish the present ground level, a suitable covered space would be provided for the boilers, engines, and dynamo machines, without causing obstruction or public annoyance, the only erection above the surface would be the chimney, which, if made monumental in form, might be placed in the centre of the square, and be combined with shafts for ventilating the subterranean chamber, care being taken of course to avoid smoke by insuring perfect combustion of the fuel used. The cost of such a chamber, of engine power, and of dynamo-machines, capable of converting that power into electric energy, I estimate at £140,000. To this expense would have to be added that of providing and laying the conductors, together with the switches, current regulators, and arrangements for testing the insulation of the wire. The cost and dimensions of the conductors would depend upon their length, and the electromotive force to be allowed. The latter would no doubt be limited by the authorities to the point at which contact of the two conductors with the human frame would not produce injurious effects, or say to 200 volts, except for street lighting, for which purpose a higher tension is admissible. In considering the proper size of conductor to be used in any given installation, two principal factors have to be taken into account; first, the charge for interest and depreciation on the original cost of a unit length of the conductor; and, secondly, the cost of the electrical energy lost through the resistance of a unit of length. The sum of these two, which may be regarded as the cost of conveyance of electricity, is clearly least, as Sir William Thomson pointed out some time ago, when the two components are equal. This, then, is the principle on which the size of a conductor should be determined. From the experience of large installations, I consider that electricity can, roughly speaking, be produced in London at a cost of about one shilling per 10,000 ampere volts or watts (746 watts being equal to 1 horse-power) for an hour. Hence, assuming that each set of four incandescence lamps in series (such as Swan's, but for which may be substituted a smaller number of higher resistance and higher luminosity) requires 200 volts electromotive force, and 60 watts for their efficient working, the total current required for 64,000 such lights is 19,200 amperes, and the cost of the electric energy lost by this current in passing through 1-100th of an ohm resistance is £16 per hour. The resistance of a copper bar one quarter of a mile in length, and one square inch in section, is very nearly 1-100th of an ohm, and the weight is about 2¼ ton. Assuming, then, the price of insulated copper conductor at £90 per ton, and the rate of interest and depreciation at 7½ per cent., the charge per hour of the above conductor, when used eight hours per day, is 1½d. Hence, following the principle I have stated above, the proper size of conductor to use for an installation of the magnitude I have supposed would be one 48·29 inches section, or a round rod eight inches diameter.

If the mean distance of the lamps from the station be assumed as 350 yards, the weight of copper used in the complete system of conductors would be nearly 168 tons, and its cost £15,120. To this must be added the cost of iron pipes, for carrying the conductors underground, and of testing boxes, and labour in placing them. Four pipes, of 10in. diameter each, would have to proceed in different directions from the central station, each containing sixteen separate conductors of 1in. diameter, and separately insulated, each of them supplying a sub-district of 1,000 lights. The total cost of establishing these conductors may be taken at £37,000, which brings up the total expenditure for central station and leads to £177,000. I assume the conductors to be placed underground, as I consider it quite inadmissible, both as regards permanency and public safety and convenience, to place them above ground, within the precincts of towns. With this expenditure, the parish of St. James's could be supplied with the electric light to the extent of 25 per cent. of the total illuminating power required. To provide a larger percentage of electric energy would increase the cost of establishment proportionately, and that of conductors, nearly in the square ratio of the increase of the district, unless the loss of energy by resistance is allowed to augment instead. It may surprise uninitiated persons to be told that to supply a single parish with electric energy necessitates copper conductors of a collective area equal to a rod of 8in. in diameter; and how, it may be asked, will it be possible under such conditions to transmit the energy of waterfalls to distances of twenty or thirty miles, as has been suggested. It must, indeed, be admitted that the transmission of electric energy of such potential (200 volts) as is admissible in private dwellings would involve conductors of impracticable dimensions, and, in order to transmit electrical energy to such distances, it is necessary to resort, in the first place, to an electric current of high tension. By increasing the tension from 200 to 1,200 volts the conductors may be reduced to one-sixth their area, and if we are content to lose a larger proportion of the energy obtained cheaply from a waterfall, we may effect a still greater reduction. A current of such high potential could not be introduced into houses for lighting purposes, but it could be passed through the coils of a secondary dynamo-machine, to give motion to another primary machine, producing currents of low potential to be distributed for general consumption. Or secondary batteries may be used to effect the conversion of currents of high into those of low potential, whichever means may be found the cheaper in first cost, in maintenance, and most economical of energy. It may be advisable to have several such relays of energy for great distances, the result of which would be a reduction of the size and cost of conductor at the expense of final effect, and the policy of the electrical engineer will, in such cases, have to be governed by the relative cost of the conductor, and of the power at its original source. If secondary batteries should become more permanent in their action than they are at the present time, they may be largely resorted to by consumers, to receive a charge of electrical energy during the day time, or the small hours of the night, when the central engine would otherwise be unemployed, and the advantage of resorting to these means will depend upon the relative first cost, and cost of working the secondary battery and the engine respectively. These questions are, however, outside the range of our present consideration. The large aggregate of dwellings comprising the metropolis of London covers about seventy square miles, thirty of which may be taken to consist of parks, squares, and sparsely inhabited areas, which are not to be considered for our present purpose. The remaining forty square miles could be divided into, say, 140 districts, slightly exceeding a quarter of a square mile on the average, but containing each fully 3,000 houses, and a population similar to that of St. James's. Assuming twenty of these districts to rank with the parish of St. James's (after deducting the 600 shops which I did not include in my estimate) as central districts, sixty to be residential districts, and sixty to be comparatively poor neighbourhoods, and estimating the illuminating power required for these three classes in the proportion of 1 to ⅔ to ⅓, we should find that the total capital expenditure for supplying the metropolis with electric energy to the extent of 25 per cent. of the total lighting requirements would be:—

20	×			177,000	=	£3,540,000
60	×	⅔	×	177,000	=	£7,080,000
60	×	⅓	×	177,000	=	£3,540,000
						£14,160,000

or say £14,000,000, without including lamps and internal fittings, and making an average capital expenditure of £100,000 per district. To extend the same system over the towns of Great Britain and Ireland would absorb a capital exceeding certainly £64,000,000, to which must be added £16,000,000 for lamps and internal fittings, making a total capital expenditure of £80,000,000. Some of us may live to see this realised, but to find such an amount of capital, and, what is more important, to find the manufacturing appliances to produce work representing this value of machinery and wire, must necessarily be the result of many years of technical development. If, therefore, we see that electric companies apply for provisional orders to supply electric energy, not only for every town throughout the country, but also for colonies, and for foreign parts, we are forced to the conclusion that their ambition is somewhat in excess of their power of performance; and that no provisional order should be granted except conditionally on the work being executed within a reasonable time, as without such a provision the powers granted may have the effect of retarding instead of advancing electric

Digitized by Google

lighting, and of providing an undue encouragement to purely speculative operations. The extension of a district beyond the quarter of a square mile limit would necessitate an establishment of unwieldy dimensions, and the total cost of electric conductors per unit area would be materially increased; but independently of the consideration of cost, great public inconvenience would arise in consequence of the number and dimensions of the electric conductors, which could no longer be accommodated in narrow channels placed below the kerb stones, but would necessitate the construction of costly subways—veritable *cava electrica*. The amount of the working charges of an establishment comprising the parish of St. James's would depend on the number of working hours in the day, and on the price of fuel per ton. Assuming the 64,000 lights to incandesce for six hours a day, the price of coal to be 20s. a ton, and the consumption 2lb. per effective horse-power per hour, the annual charge under this head, taking eight hours' firing, would amount to about £18,300, to which would have to be added for wages, repairs, and sundries, about £6,000, for interest with depreciation at 7½ per cent. £13,300, and for general management say £3,400, making a total annual charge of £41,000, or at the rate of 12s. 9½d. per incandescence lamp per annum. To this has to be added the cost of renewal of lamps, which may be taken at 5s. per lamp of 16 candles, lasting 1,200 hours, or to 9s. per annum, making a total of 21s. 9½d. per lamp for a year. In comparing these results with the cost of gas lighting, we shall find that it takes five cubic feet of gas, in a good argand burner, to produce the same luminous effect as one incandescence light of 16 candle-power. In lighting such a burner every day, for six hours on the average, we obtain an annual gas consumption of 10,950 cubic feet, the value of which, taken at the rate of 2s. 8d. per 1,000, represents an annual charge of 29s., showing that electric light by incandescence, when carried out on a large scale, is decidedly cheaper than gas lighting at present prices, and with the ordinary gas burners.

On the other hand, the cost of establishing gas works and mains of a capacity equal to 64,000 argand burners would involve an expenditure not exceeding £80,000 as compared with £177,000 in the case of electricity; and it is thus shown that, although it is more costly to establish a given supply of illuminating power by electricity than gas, the former has the advantage as regards current cost of production.

It would not be safe, however, for the advocates of electric lighting to rely upon these figures as representing a permanent state of things. In calculating the cost of electric light, I have only allowed for depreciation and 5 per cent. interest upon capital expenditure, whereas gas companies are in the habit of dividing large dividends, and can afford to supply gas at a cheaper rate, by taking advantage of recent improvements in manufacturing operations, and of the ever-increasing value of their by-products, including tar, coke, and ammoniacal liquor. Burners, have, moreover, been recently devised by which the luminous effect for a given expenditure of gas can be nearly doubled by purely mechanical arrangements, and the brilliancy of the light can be greatly improved.

On the other hand, electric lighting also may certainly be cheapened by resorting, to a greater extent than has been assumed, to arc lighting, which, though less agreeable than the incandescence light for domestic purposes can be produced at less than half the cost, and deserves on that account the preference for street lighting, and for large halls, in combination with incandescence lights. Lamps by incandescence may be produced hereafter at a lower cost, and of a more enduring character.

The latter portion of the address referred principally to the question of heating by gas, Dr. Siemens stating that probably electricity would provide light, and gas would provide heat.

THE SOCIETY OF TELEGRAPH ENGINEERS.

The first meeting after the summer recess was held on Thursday, November 9, in the theatre of the Institution of Civil Engineers, Great George-street.

After the formal business of the meeting, a contribution by Colonel F. Bolton was announced. This gentleman has continued his list of electric light patents to a very recent date, and it will be seen that the introduction to this new list paid a well-deserved tribute to the management of the Society's library, in the hands of Mr. A. J. Frost. The introduction to Colonel Bolton's list was as follows:—

Some Further Historical Notes on the Electric Light, bringing the Subject up to the 30th September, 1882.

The paper on "Electric Lighting" which I had the honour to read before the Society in May, 1879, met with so favourable a reception, while, as I am assured, it has not been without value to those interested in the subject, that I have been encouraged and induced to continue the work, with a view to bringing it down as far as possible to the present time. In 1879 the conditions were different from what they are now. Then the subject of electric lighting was comparatively a new one, and the number of specifications to be examined, although extending over a number of years, was considerably less than the number issued between 1879 and the present year of grace. From an historical point of view my former paper necessarily possessed far greater interest for the student than the present one can possibly do, as it embraces so brief a period.

I have unavoidably been led to deviate in some respects from the plan formerly adopted, and to make this paper of a somewhat more practical character, in the desire to assist the student in his investigation of that particular system of electric lighting which may happen to be the subject of his search.

The abstracts of specifications given under each heading do not pretend to be even a *précis* of the whole of each patent. Indeed, such a compilation would be entirely beyond the scope of this paper or the limits allowed by the Society's *Journal*. The number of patents which have been taken out since the date of my last paper has been so great, exceeding 550, as to almost cause me, when I found the mass of work to be done, to hesitate before continuing it; nor should I have done so had I not known the great difficulty there is in obtaining even a mere list of the numbers, dates, and titles of the various patents on any particular subject, and therefore believed I could not fail to render some slight service to electrical engineers by undertaking this task.

Although in 1879 electric lighting was beginning to create considerable interest in the public mind, it had not assumed the vast importance it now possesses. The enormous amount of capital that has lately been embarked in various electrical undertakings, and the great number of persons not electricians who are connected with the subject, render it more than ever necessary that some system of classification should be attempted. It might well be thought that such a work should properly be performed by the Commissioners of Patents, who have the funds and all the material at their disposal for the purpose. Apparently its desirability, not to say necessity, has failed to strike them. It is true that an abstract of specifications on electric lighting has been issued by the Patent Office, but, although a recent publication, it only goes up to 1876. It will, probably, be admitted, therefore, that its usefulness is very much impaired, and, however thankful we ought to be for small mercies, we have not here much to be thankful for.

The limited time that I have been able to devote to the matter, and the great difficulty that exists in making a satisfactory classification of the immense number of patents produced during the last few years, have rendered the work one of great labour and considerable difficulty. I can only offer the paper as supplementary to the previous one, in the hope that the mere fact of bringing the various systems under one heading, with a few necessary subdivisions of all the published specifications to September 30, 1882, may prove of value to those who, in large and daily-increasing numbers, are devoting their attention to the subject of electric lighting.

I would here refer to the great assistance I have derived from the valuable collection of electrical patents presented to the Society by H.M. Commissioners of Patents. I have thereby been enabled to have laid before me week by week the whole of the published specifications on electricity and magnetism as soon as they were issued to the public, a fact which, I think, speaks well for the management of our library.

I would, however, suggest that, if the specifications were classed under their various headings, and bound up, or a classified index of them made, the labour of searching for any particular patent would be considerably lessened.

Mr. W. H. Preece, F.R.S., on the Munich Exhibition.

We do not intend to follow Mr. Preece *seriatim* in his paper, because we are already dealing with the exhibition in our other columns. We all know and admire Mr. Preece's ability to interest his hearers, and can say that this description of his visit to Munich was given in his best style. The paper, though long, did not weary, inasmuch as it was lightened by many asides and sly allusions to controversial points. We came in for our share of criticism, inasmuch as we had the temerity to "joke" the *Saturday Review* for its ignorance of Messrs. Ruston, Procter, and Co. We have wondered whom the *Saturday Review* writer might be—and whoever he is we can only say he sinned in good company—for Mr. Preece acknowledged that the firm mentioned was not particularly well known to him. The Munich Exhibition, although termed international, was so only in name—nor, indeed, was it really national, when such firms as Siemens and Halske, Felten and Guilleaume, &c., were unrepresented. It was, indeed, South German-Bavarian—intensely so. There was little new to chronicle, and that little of no very great importance. Great praise was given to Messrs. Crompton as having an excellent exhibit, and being the only English representatives at the exhibition. The Edison installation was noticed, as was that of Schuckert, whose machine was well spoken of. A secondary battery of an old type with a new name, and giving off in process of making a nauseous smell was mentioned, as was the new-old incandescent lamp with filaments like those of Swan, only shaped and interwoven spirally. That, with the hollow carbon, and other exhibits have already been mentioned in our columns. The lead-covered cables of Berthould and Borel were spoken of also as a new-old arrangement.

The archæological exhibits of the instruments of Sommering, Steinheil, Reis, &c., were mentioned, and so on. Reference was made to the phosphor bronze wires exhibited by M. Weiller, an exhibit which we have not yet mentioned. Mr. Preece seemed to think very favourably of this wire, and stated that a wire, 14½ B.W.G., was exhibited which would stand a strain equal to a similar wire of steel, and had a resistance similar to that of copper.

Mr. Preece insisted upon the fact that the Munich Exhibition would be known more on account of the tests carried out than for the apparatus exhibited. He justly spoke of the able men who undertook the work of testing as admirably fitted for their self-imposed task, as energetic, and greatly interested in the work. The testing instruments were all arranged previously to the opening of the exhibition, and so arranged that the crucial tests could be taken at the same time. The results are not yet ready, but will, no doubt, be shortly.

A hearty vote of thanks was given to Mr. Preece, subsequent to a short discussion, and the President announced that at the next meeting he should give a description of the experiences of the telegraphic work during the late campaign in Egypt.

THE ORIENTAL TELEPHONE COMPANY (LIMITED).

An extraordinary general meeting of the members of this Company was held at the City Terminus Hotel, Cannon-street, on the 13th November, 1882, under the presidency of John Pender, Esq., M.P.

The Secretary (Mr. W. G. Hall) read the notice convening the meeting, and subsequently the minutes of the last meeting, held on the 19th April, 1882, which were approved by the present meeting and signed by the chairman.

The Chairman then said: Gentlemen, the objects of calling you together to-day are, first, to ask you to confirm a sale of our rights to a company formed in Bombay, and secondly, to take powers to make similar sales elsewhere without the necessity of a special meeting. When I last had the pleasure of addressing you, I find, on referring to the speech I made on that occasion, that I made the following remarks: "We have not yet attempted any sales of privileges which we hold in India, but I expect before long (having established these important exchanges in the important

Digitized by Google

centres of commerce I have mentioned, and looking to the number of the places which the Government wish us now to extend our system to) we may adopt the principle which has been adopted in England of forming small companies who will pay us a certain sum for the privilege which we possess, and that we shall also, at the same time, retain a certain interest in the working of those companies. That is the mode by which we propose to extend our system in India, keeping down our capital account, and basing our extensions on the creation of companies who will find the capital to carry on those extensions." The object to-day, as I have stated, is to ask you to confirm an agreement which we have made with a local company in Bombay for the purpose of carrying out our system in that presidency. We are to receive for our interest there in cash £30,000, and in shares £30,000, less certain expenses, which latter will continue, of course, in our possession. This gives us the advantage of local interest in carrying on the work, it gives us a very fair sum to begin with, and it also gives us about half of the working interest in that concern. Pursuing a different policy from certain other companies who have sold their interests before proving them in any place, we have thought it better to prove our system, showing people the benefits which are likely to arise from working it. That is the policy we have adopted, and the meeting to-day is to confirm the first important sale or arrangement in that direction. Before asking the solicitor to read the agreement I think it right that I should give you a short history of our present position, not only in Bombay, but in other parts of the East where we have established it. In Bombay we have something like 70 subscribers. They will be handed over to the new company, and I have no doubt that they will very soon make a very different show in the number. We have also secured as customers the municipality, the police, and the fire stations. We expect, too, to make communications for the Government, and where the Government take up a system it is generally an acknowledgment of its utility, and, consequently, others follow; and we know, as a rule, that wherever one merchant takes it up another must follow. In fact, it is one of those systems which is so concentrative that it becomes a positive necessity in a large commercial town that every commercial house should be in connection with the exchange. We therefore look forward to very marked success when it is, under local management, in the hands of men deeply interested in its promotion. In Calcutta we are endeavouring to follow out the same course; but any one who knows anything of India and of the peculiar mode in which India is governed will sympathise with us in the difficulties we have to contend with as regards the Indian officials. Unfortunately the English in India believe they should be omnipotent in everything, and it is very difficult indeed for what they call interlopers to have anything like a fair chance of pushing forward their interests; but I am happy to say that the present Indian Government—not only those at the head of the Government in India, but also those at the head of the Government in England—the Indian Government have taken a very different view, and are determined to pursue a very different policy. They have given me most positive assurances that we shall have fair play, and although we have taken a good many months to bring that about I believe eventually the small executive will be obliged to succumb to the large executive in enabling us to carry out our system. I may, however, mention that in Calcutta at the present time we have something like 100 subscribers. I hope the next time I meet you I shall be able to announce the formation of a company there. At Madras we have 30 susbcribers. The Government, however, are now having the system applied to their offices, and, therefore, we expect some more rapid extension there, but Madras is not celebrated for going very fast even as compared with the other presidencies. In Rangoon our last advices state that we have twenty-one subscribers there, and twenty-four police and post commissioner lines. This place also promises an increase. Kurrachee has been so far disappointing. Still, when the telephone is once introduced, and in such a climate, we cannot but be hopeful that it will be universally taken up by the mercantile community. In Colombo, Ceylon, we have thirty subscribers, and we anticipate a very considerable increase there. In fact, I believe it may be carried there to a much larger extent through connecting the different coffee estates which are working and putting them in connection with Colombo. In China we are making progress, but there also we have not gone quite as far as we expected. We found some of the merchants and some of the people there endeavouring to work a system among themselves. That is now at an end. It is being formed into one body now, controlled by us, and I hope, ere long, we shall be able to establish in China—at Hong Kong and Shanghai—independent companies. In Shanghai we have seventy-three subscribers. At Singapore we have a very active system going on. That system was well inaugurated by the manager of the Company—the Eastern Extension Telegraph Company—which I have the honour to represent. Our active and energetic manager there thought, as I have always said, that the telephone would be a feeder to the telegraph, and he established what has turned out a very successful system, which we purchased at little more than cost. We had to pay something to a few persons connected with him, and something for the work done, but, as far as the materials are concerned, we paid the cost only—£2,990—in cash, and an equal sum in fully paid £1 shares in this Company. At the present moment there is a gross revenue of £1,600, and a net revenue of £1,100, so we have a return on our investment. There I may mention there are about seventy subscribers. The place where we had made greater advances than anywhere else was Egypt, when the unfortunate crisis took place, but I am glad to say that we are almost already in good working order there again. The Government have taken it up. It was proved to be of very great use during the time the Admiral had possession of Alexandria—so much so that he addressed a letter of thanks to the Company's agent for the great use the telephone proved to him during the time of the occupation. We shall also, I have no doubt, be recouped by the Egyptian Government for the injury and loss we sustained during the crisis. At Cairo our system is connected with the palaces and different offices, and we have sixty subscribers there. At Alexandria we have ninety-four subscribers and twenty-one connections with the Government offices. We hope in a very short time to establish an independent company there. We have received a letter to the following effect:—"The reinstatement of telephonic communications in Alexandria is approaching completion, and by next mail I hope to send you a list of subscribers connected up. It is a sign of the progress of the telephone to be able to state that notwithstanding the revulsion of affairs in Egypt we have virtually not lost a subscriber." We all know the destruction that took place at Alexandria of house property, and consequently we have a good deal before us when the city is rebuilt. I therefore look forward to Egypt being a very important station indeed. We have, notwithstanding the state of things which has prevailed there, received a first remittance. It is not a large amount, it is true, but it is the beginning of money coming from Egypt, and no doubt once started we shall be receiving it steadily. The first system that we had opened, which we took over from the vendors, was in the Hawaiian Islands, and our agent there, writing on the 21st of September, stated, with regard to the exchange at Honolulu, that there were 232 subscribers connected, and applications from 30 more. Well, that is in a place where we could scarcely expect such a number of subscribers, and it seems to be growing as fast as the other places. I think you will agree with me that, looking to the very favourable field we occupy, the development of the business is only a question of time. Sir Julius Vogel is in Australia now, and is looking up that part for us; but the fact is that altogether we have about as much in hand now as our capital enables us to deal with. We have only had £60,000 in cash to carry on the work, and until we sell some of these systems, so as to get a return, such as we are getting from Bombay, we think it is not desirable to push the business unduly so as to place us under the necessity of making a call on the shareholders. We think we can meet those requirements better, and, perhaps, in a more agreeable way to the shareholders by issuing 20,000 of the shares which we kept back from the vendors in the settlement with them on account of some irregularity. We retained 25,000 of those shares, and we propose to issue 20,000. Those shares to-day are quoted at something like 16s. in the market, and we propose to issue them at 12s. 6d. in other words 2s. 6d. above par, giving the shareholders the opportunity of taking them *pro rata* according to their holdings. That will give us something like £10,000—for there is only 10s. paid up on our shares—and with the sum coming to us from Bombay I hope we shall be able to pay our first dividend to the shareholders. That will probably be after the end of our financial year. These remarks will give you some idea of our position, and I will now give you these details: At Alexandria we have 94 regular subscribers, 21 Government subscribers, and there are applications for 17 more. That is altogether 132. At Cairo we have 60 subscribers. At Bombay we have 73, and eight for the military, police, and other stations, making together 81. In Calcutta we have 108 subscribers. At Madras we have 30 and four for the Government, making together 34. At Rangoon we have 21 subscribers and 15 for the Government, being together 36. At Kurrachee there are 15 subscribers, at Colombo 30, at Hong Kong 15, at Shanghai 73. At Singapore we have 38 subscribers, and 32 for the military, police, and others, together 70. At Honolulu we have 232 subscribers, and 57 more applications, making together 289. The total number of subscribers, connected, or who have applied, therefore, is 943. That is the position, gentlemen, we occupy to-day. The solicitor will now read the agreement with the Bombay Company.

The SOLICITOR (Mr. A. G. Renshaw) having read the agreement,

The CHAIRMAN said: Then the resolution is as follows:—"That this Company hereby approve, ratify, and confirm an agreement dated the 8th of August, 1882, and made between Clement Davidson Leggatt, as the agent of this Company in India, of the one part, and John Grey Russell, as the trustee for and on behalf of a company then about to be formed and incorporated under the name of 'The Bombay Telephone Company (Limited),' of the other part, whereby it has been agreed, subject to confirmation by this Company, to sell the business, goodwill, plant, and property of this Company in the Bombay Presidency, Scinde, and Hyderabad (Deccan), to the said 'Bombay Telephone Company (Limited);' and do hereby authorise and require the directors of this Company to carry such agreement into effect, either with or without any modification or new terms which they may agree to on behalf of this Company."

Mr. PATRICK CARNEGY (a director): I have the pleasure of seconding that resolution.

The CHAIRMAN: Before I put that, if any gentleman has any remark to make, I shall be glad to hear him.

Mr. ST. JOHN ACKERS: Is there any real meaning in those words in the agreement as to "native States?" There is nothing in the resolution about native States, but the agreement says there shall be the right to the Bombay Company to sell, or whatever the term may be, the right of the Company in native States of India. That is not mentioned in the resolution.

The CHAIRMAN: The resolution is to approve the agreement we have made with the Bombay Company—the agreement you have heard read. The limit of the Bombay Company is given in that agreement.

Mr. ACKERS: Then that extends far beyond the resolution. The resolution mentions certain places—for instance, Bombay, Scinda, and Hyderabad (Deccan). Do I understand that those are native States?

The CHAIRMAN: They are included in the agreement with the States the Bombay Company has the right to work.

Mr. ACKERS: All over India?

The CHAIRMAN: No, not all over India. They are confined to these places. We have the work at Calcutta and Madras, but this is what belongs to the Bombay Company.

A SHAREHOLDER: It is rather indefinite—what this gentleman refers to—the allusion as to the native States of India. It struck me at the time it was being read that that was rather indefinite. I said to a gentleman next me, as to the words "native States," that means all India. I think it advisable that the solicitor should look to that part, and point out whether I am correct or not.

The CHAIRMAN: "Native independent States." This is very much in the position of a gentleman who has a private domain. They are entitled to put up the telephone in such places. In fact, the more they put it up in these outlying places the more money we shall get.

In answer to Mr. ROBINSON KENDAL,

The CHAIRMAN added: What is meant is an independent State not under the rule of the English Government. It is very much in the position of a gentleman who has an independent property in India. The Bombay Company will be entitled to deal with such gentlemen.

Mr. KNIGHT: The native States of India are very numerous. Some are under the political control of the Supreme Government of India, and others are under the control of the Bombay Government. In the agreement with the Bombay Company, I should think by "native States" you meant those States within the control of the Bombay Government. The State of Hyderabad is not under the control of the Bombay Government, but under

Digitized by Google

the political control of the Supreme Government of India. I should think, as the agreement was read by the solicitor, that the expression "native States of India" would mean all the native States unless qualified by some words to the effect that they were such native States as are under the control of the Bombay Government. I do not know whether it would be of any great importance, because I do not feel sure that our patent laws run to any of the native States. The matter ought to be defined whether it means all the native States of India or only those under the political control of the Bombay Government.

The CHAIRMAN: I think you must take this view of it. These are what we call independent States. They are independent so far as their revenues are concerned, but they are subject, more or less, to the supervision of the British Government. They are outlying places which it is very material to us to have worked. It would be impossible for us to form a company to work those places alone, and as we are proprietors of a very large portion of the Bombay Company's capital the more of those places they choose to take up the better for us, as we shall get a greater revenue out of it. If we go to Calcutta we shall take a radius in the same way, but the great thing is to get these, what we call independent native States, worked. They are apart from one another, and it is necessary to have them worked by one organisation, and we believe it will be better that they should be worked by the Bombay Company, as we believe there is more enterprise there than in any other State in India. The more those places are worked the greater the revenue that will accrue to us. If they find they make a good bargain there we get half of all they make, and I cannot see that there is anything very far wrong in giving them the run of what they call independent States. Again, in those independent States those who first get possession will derive the greater benefit, because I am informed that those native States do not grant patent rights as they do in other places in India. Therefore the sooner they are occupied the better for the possessors. This matter must have been well considered in Bombay, where this agreement was drawn, so as to get the greatest amount of revenue for the Company.

Colonel GOURAUD (a director): I think that the importance of the question raised is entirely covered by the fact of our possessing such a large interest in that company. If we were not shareholders in the Bombay Company, I don't think we could over estimate the importance of the question raised, but being the largest shareholders—having half of the capital—the wider the Bombay Company extends its operations the better for us. It furnishes the capital, and we have half the profits. I should like now to depart from the usual course on such occasions, and say a few words rather as a shareholder than as a director. My excuse for this will be perhaps better understood if I refer to my large interest as a shareholder in the Company, and to the fact that I have taken an insignificant part in the negotiations which have resulted in the sale of these rights to the Bombay Company. But for that I should scarcely venture to state what I am going to say. The explanation of my taking no part on the working of the Board of that company is due to the fact that I was not in the country when the negotiations took place. On my return, it being the first sale of the concessions of the Company, and it being the beginning of the policy pointed out by the chairman at the last meeting, and being so largely interested as a shareholder of the Company, I made, perhaps, what was an exceptional investigation of all the terms of the contract. I have had opportunities of doing so such as no other shareholder has had, naturally, and I have done so very thoroughly; and I am happy to say—and you will be all glad to hear it from me as a shareholder and not as a director—that it is a favourable contract for this Company. My opinion may carry some weight on that point when it is taken into account, as it may be, that I have had something to do with all the telephone contracts made since the birth of the telephone; and I regard it as an especially favourable augury for good that on behalf of this Company your directors have been able to form a Company on the terms on which this Company is formed, and with the excellent local support it has received on the part of the Bombay merchants who have joined the Board, who are responsible to the public for the issue, and who will be really responsible for the management in Bombay. While we congratulate ourselves on the arrangement we have made, we must be careful that those self-gratulations shall not be construed by the parties on the other side into meaning that it is a hard bargain for them. They, perhaps, will hear what we say, but this is one of those cases where both parties give and take. We had something to give—something they wanted, something they could not get on without. This may seem a broad statement, but I make it in the full breadth of its possible meaning: There is, I contend, no civilised body in the world that can get on without telephonic communication. Therefore they wanted it, and we agreed on what terms we would give it to them. They gave us, on the other hand, the inestimable advantage, where the business is conducted so far from home, that feature on which the chairman touched, namely, the advantage and importance of local support. That if in right hands ensures the success of an enterprise like this, and that statement has the broadest possible authority. The telephone, as you know, came from America. The Americans who brought it here (I happened to be one of them) did not seek to carry it out themselves. We did it as far as we could—as far as our means allowed; but as soon as we inaugurated it, and showed what it was, as this Company has done in Bombay, we looked for gentlemen to take it off our hands. We still hold a very large interest in it. That fact has explained the great success the telephone has had here. I venture to say that this Bombay Company will be a very great success. I cannot see how it can possibly fail. Having said so much from the shareholders' point of view, I wish to say one or two words from the directors' point of view. I wish to say them to the shareholders of the Company, and I presume I am speaking to shareholders in a good many other telephone companies, and it is this: There is one thing not generally appreciated or understood in this telephone business. It bears with great significance on the value of telephone share property, and when I say telephone share property I rather mean that class of telephone property whose business is chiefly, if not exclusively, what is known as telephone exchange business. It is this—that where you once establish a telephone exchange in a mercantile community you have got the safest kind of investment for your money, for this reason, no one who ever uses the telephone for business purposes gives it up unless he goes out of business by reason of making his fortune or by reason of bankruptcy (and there are more people who use the telephone who go out of business through making their fortunes than retiring from the other cause). It is a fact noticed by the United Telephone Company—of which I am a director—that in not a single instance where a party has subscribed to the exchange has he ceased his subscription because of the telephone being of no use to him. There is not a single instance of that in my experience, and I say this on the strength of considerable experience, since the beginning of the telephone, and as a director of half-a-dozen telephone companies, whose operations extend round the world. There is the further fact, too, of the impossibility of competition. I know of no monopoly in business that is so certain a monopoly as the telephone business, for the reason that there cannot be two telephone exchanges. Generally monopolies are considered objectionable, but this is a kind of monopoly essential to the interests of the people who use it. Hence it is a monopoly with the very best security. As an illustration of the argument—it is the first time I have made it, and I have never heard it anywhere—I may mention that in a foreign concession which I have recently been one of a party to acquire, the Government has actually stipulated that it shall be a monopoly—an exclusive concession for ever, as long as the business is done. That bears very great significance on the value of telephone share property, and it is a good thing for all of you to know it. None of you can ever lose money by knowing it, and some of you may make money by the knowledge. I support the resolution on behalf of some 60,000 odd shares in the Company.

Mr. KNIGHT: I did not rise to object to the resolution. I saw there was some uncertainty in the meeting as to what was meant by "native States." I think you said that the enterprise of the Bombay community was very favourable to this enterprise, and, as we hold so large an interest in the Bombay Company, I am not a party to object to the concession covering all the native States, only I think it should be understood that that is so.

The CHAIRMAN then put the resolution in the usual way, and declared it carried unanimously. Continuing, he said: The next resolution I have to propose is as follows:—"That the clause or sub-section marked (*c*), contained in the 60th of the Company's Articles of Association be repealed, and that, in lieu thereof, the following shall henceforth stand and be the clause or sub-section marked (*c*) contained in the said 60th Article—that is to say:—'(*c*) They may of their own authority sell all or any part of the business, goodwill, patents or patent rights, and property of the Company, or the business, goodwill, patents or patent rights, and property appropriated for, or appertaining to, any branch of the Company's business, either wholly or partially, for cash or for shares, debentures, or other interests in any company or corporation, or to any person or persons; and if deemed expedient the directors may hold or (so that the capital of the Company be not thereby reduced) distribute in specie among the members in proportion to their holdings, or otherwise deal with such shares, debentures, or other interests.'"

Sir A. ARMSTRONG: I beg to second that.

Mr. ROBINSON KENDAL: I understood you to say that you had withdrawn from the vendor 20,000 of the vendor's shares.

The CHAIRMAN: Yes.

Mr. KENDAL: And that you now propose to issue them to the general body of the shareholders. I understood that those vendor's shares were in the nature of deferred shares, not entitled to dividends as ordinary shares. If that be so—and I speak under correction—I wish to know how you are going to issue those deferred shares. Have you the power to do so?

The CHAIRMAN: I think that is a very proper question to put, and the solicitor will explain it, but we should not have proposed to you to-day to issue those shares unless we had taken the best opinion as to our ability to do so. We are quite justified in issuing these shares, because they are really original shares, and have never been issued. We simply retained them. We did not pay them away, and they stand in our possession as original shares. I am very glad you have put the question, and I believe that the solicitor will give you an opinion that will satisfy the shareholders.

Mr. KENDAL: While I am on my legs may I ask you to say, *ex cathedra*, what is the exact position of the ordinary shares and the deferred shares of the Company. I have had at least a dozen conversations with gentlemen as to their position, and as to whether the deferred shares get nothing for six years or some other period.

The CHAIRMAN: The vendor's shares are deferred shares, or shares upon which they are not to receive any income for five years. The shareholders must receive 6 per cent. before they can receive anything, and that is deferred for five years. If we were to earn 12 per cent., the deferred shares would get 6 per cent., but they cannot get anything for five years unless the shareholders during that five years have received 6 per cent. on their shares.

A SHAREHOLDER: Does that mean if the ordinary shareholders receive 6 per cent. for five consecutive years that then the deferred shares would get a dividend, or does it mean that, no matter what dividend is paid on the ordinary shares, the deferred shares shall not be paid till the end of five years?

The CHAIRMAN: At the end of five years the deferred shareholders come into payment with the ordinary shareholders. That is, if the ordinary shareholders have received 30 per cent. They must receive 30 per cent. before the deferred shareholders receive anything. I think it would be well for the solicitor to read counsel's opinion as to the shares, so that the public may be perfectly assured that these shares now proposed to be issued are in precisely the same position as the ordinary shares.

A SHAREHOLDER: Suppose 60 per cent. could be distributed in the five years, what would become of the remaining 30 per cent.?

The CHAIRMAN: The ordinary shares must receive 30 per cent. before the deferred shares receive anything. After we have received 30 per cent., then, if we can afford anything over that 30 per cent., the deferred shares get their proportion.

Mr. KENDAL: Suppose you earn 30 per cent. in two years, will the five years' clause be abrogated at the end of that two years?

The CHAIRMAN: Certainly. After we pay 30 per cent. the deferred shares come in.

The SOLICITOR: The Company was constituted with a capital of £300,000, divided into 300,000 shares of £1. There were no deferred shares under the Memorandum of Association of the Company. The deferred shares were only made such by the contract with the vendors, and, therefore, when that contract was modified the shares became, as before,

Digitized by Google

ordinary shares of the Company. If you like I will read the opinion of counsel, which we took some time ago when these shares were reserved from those issued to the vendor. He then read the opinion.

Mr. ACKERS: Before the motion is put I should like to ask who the present directors are?

The SECRETARY: The present directors are Mr. Pender, M.P., Sir Julius Vogel, Sir A. Armstrong, Sir William Thomson (*ex-officio*), Mr. Patrick Carnegy, Mr. James Pender, Mr. John P. Bigelow, Mr. W. W. Cargill, and Colonel Gouraud.

The CHAIRMAN: The gentleman who has put that question to me called on me the other day and remarked that there were three other names originally in the prospectus—Mr. Thomas Alva Edison, the Hon. G. G. Hubbard, and Professor Bell. Those are the gentlemen whose names are so much associated with the telephone. It appears that, according to our rules, a director must give certain attendances within six months, or otherwise he ceases to be a director. Those three gentlemen gave their names to the Company simply on account of their association with the patents, but as they live in America it was impossible that they could come over and attend our Board meetings. Their names were necessarily, in accordance with the Articles of Association, dropped out, but if it is desired by the shareholders I believe that those gentlemen would be only too glad to remain as honorary directors by our re-electing them, or altering the Articles of Association of the Company, so as to make them permanent directors. That is the simple reason why they are not now on the Board.

Mr. ACKERS: If that is carried out I shall be most thoroughly satisfied. I have the greatest possible confidence in the English directors—in you and all connected with you. At the same time I am more especially interested with the names of those gentlemen who started the telephone, and who are mostly resident in America. Their names, I believe, give additional weight and confidence to the working of our Company, and if you do what you suggest, either retain their names or alter the Articles of Association, I shall be satisfied. I think there is an unintentional inaccuracy in what you stated. They do not absolutely cease to be directors if they do not attend, but only if they absent themselves without leave. If you give that leave, except when they are in England, they will be reinstated. We owe much to the Americans, and, with your explanation, I hope that these gentlemen may continue to be directors of the Company. I trust also in your discretion, and the discretion of the rest of the Board, the arrangements you may make with other companies may be equally successful with those made at Bombay.

The CHAIRMAN: I may say that there never was any consent asked by these gentlemen for their absence. I may add that this has occurred during my absence in America. I have been to America myself and have seen them, and the opinion expressed by the gentleman who has just spoken I quite agree with. I also entirely agree with the sentiment he expresses, and I believe if I had been at the Board this would not have occurred. I think men whose names are so honourably associated with the starting of the telephone system are men whom we should keep among us even as honorary directors, showing that they still feel an interest in the growth of their children. I have not been back a fortnight, and if you had asked me the question I should have said that these gentlemen were on the Board. Now that attention has been drawn to the subject, I shall take care, unless these gentlemen have some objection, that we re-establish their names on the Board. I think we will, if you wish it, do so now. I beg to move that those gentlemen be reinstated on the Board.

Mr. ACKERS: May I be allowed to second that?

Mr. KENDAL: I think you cannot do this. The Act of Parliament especially stipulates what you can do.

The CHAIRMAN: Perhaps that is so, but this is an expression of our opinion. Before I close the business of the meeting I may mention that, during my visit to America, I had occasion to see a great deal of the telephone, and I was struck with the extent to which it is used there. In fact, it seemed to be so much employed that if you wanted any little information you got it almost immediately through the telephone. It caused me to look to statistics as to the telephone generally throughout the world, and there is a little book just published that I would draw your attention to. It is in French, and it is called the "Compagnies Internationales Telephones." I find on looking to that little pamphlet that in America—and they state that they cannot get the information there accurately—there are 37,187 telephones; but it is stated that this probably only represents one-third of the telephones used. As a matter of comparison they give at the same time the number used in Great Britain, and that is stated at 4,946, while they have got for us in India 700. I have told you that to-day our number is 943. But when you see the use of the telephone in America, and see how very few there are in use in this country and in India, I think I may say there is a very wide field for telephonic enterprise.

DR. JOHN RAE: I have just returned from a new city, Winnipeg, and I can assure you that the telephone is in large use there. A friend of mine was asked to dine a couple of miles from town, but the weather turned out very bad, and just as he was about to start he received an intimation by telephone—this was two miles from town—that they did not expect him. Winnipeg was nothing but a village two or three years ago, but now it has 25,000 inhabitants. They have the telephone everywhere, and the electric light is just starting. That bears out all that the chairman has said.

The CHAIRMAN: From what I saw in America I felt a little ashamed that we are so much behind in this thing. I was at Winnipeg, too, and saw electricity going ahead very considerably.

A SHAREHOLDER: Will you allow me to suggest that the second resolution has not been put?

The CHAIRMAN: I beg your pardon, we were getting into rather a conversational state. He then put the resolution, and declared it carried unanimously—adding that that finished the business of the meeting.

A SHAREHOLDER: I beg to propose a hearty vote of thanks for the able manner in which you have presided over us.

A SHAREHOLDER: I beg to second that.

The CHAIRMAN: I am very much obliged to you on behalf of my colleagues and myself. We have given you all the information in our power, and we have shown you that there is a very wide field for telephonic enterprise. It is the youngest of what are called the electrical children—younger than the light; and I hope as we meet from time to time this Company will show the expansion which the extensive field it is occupying would warrant us in expecting.—The proceedings then terminated.

THE BRUSH MIDLAND ELECTRIC LIGHT AND POWER COMPANY (LIMITED).

An extraordinary general meeting of the shareholders of this Company was held at the Cannon-street Hotel, on the 14th inst., "to consider the adverse proceedings taken by certain shareholders against the Company, and to pass a resolution authorising the directors to continue the business of the Company, notwithstanding the proceedings of the dissentient shareholders." Mr. R. H. Glyn presided.

The SECRETARY (Mr. H. N. Myers) having read the notice convening the meeting,

The CHAIRMAN, in the course of his address, said: Certain shareholders—and I am glad to say they are small in number and represent only a small amount, in fact eighteen shareholders out of over 800, representing only 149 shares—taking advantage of what they allege to be a misstatement, or I should say a material misstatement, in the prospectus, thought fit to bring actions against us for the return of their money. I daresay some of you have noticed—probably with no very great pleasure—that a petition in Chancery was filed to wind up this Company. This, however, was done by a friendly and a large shareholder, who has no wish whatever to wind up the Company, but who does not wish that these 18 gentlemen should come in and get any priority of claims over the rest of us supposing that this statement in the prospectus turns out to be material and we are ordered to return the money. All this fuss and bother has come from a word used in the prospectus—the word "exclusive." It was stated in the prospectus, which was issued in May, that the Company was going to buy an exclusive concession for two things from the Anglo-American Brush Electric Light Corporation—a dynamo machine and the Lane-Fox lamp. Now it is not, and cannot be, denied by any one that we have the exclusive right to that very valuable concession of the Brush dynamo machine, but it is pretty nearly clear, I think, that we have not the exclusive right to the use of the Lane-Fox lamp. The first question that will naturally arise is, how came we to say that we had, if we had not, an exclusive right to it, and it is very hard to answer this question. Whether the Anglo-American Brush Corporation purposely suppressed the fact that Mr. Lane-Fox had given a license, I think it is to the British Electric Light Company, or not I do not know. Whether they did it in innocence, not knowing what they were selling, I do not know; but it is quite clear that we have only a *pari passu* right with the British Electric Light Company to the use of the Lane-Fox lamp in our district. There is another very remarkable feature in this matter. On the Board of one, if not more than one, of the companies who have used this word "exclusive" are directors who are directors also of the parent Brush Company. If any one can be made to suffer for this mistake it shall be done. Another curious fact about the mistake is that it passed so many solicitors of high standing, and I take it that the reason for that fact was this—you must understand distinctly that we never paid a single farthing for the Lane-Fox lamp. What we paid for was that very valuable concession of the Brush dynamo machine, not a cent for the Lane-Fox lamp, and I take it that the real secret is that the solicitors, saying that "they have paid nothing for it," did not go so carefully into the rights as they might have done. We have not lost sixpence from the want of this exclusive right. There are two courses before us in consequence of these actions—one is liquidation and the other is going on. Now I do not think many gentlemen here can consider the sound of the word "liquidation" is pleasant; and how should we stand if we were to liquidate? We should have, first of all, a certain amount of machinery—call it £6,000 worth, and then our great asset would be our concession from the Brush Company. Now, I do not think any one at present would give any large sum of money for an electric light concession, because we know that electric lights are rather in low water at present, and in the hands of a liquidator would not fetch much. If, therefore, we were to liquidate, it would, putting aside something I shall tell you about presently, be suicidal—indeed idiotic. Now we come to the other alternative—shall we go on? And the first question that arises is what we have done up to the present time? The prospectus was issued in the middle of May, and of course it took a long time to get it into ship-shape. We had to get agents, and officials, and that sort of thing, and I may fairly say that we have been actually working for only four months. In those four months we have actually paid our working expenses, and those expenses include not only advertising and the running about to get orders—because up to the present time people have not been asking us to put up the light, we have to go to them for that—but it also includes several installations we have been obliged to make as advertisements in various places—Boston, Leicester, Reading, Gainsborough, and Grimsby, and we found it absolutely necessary to show that our light would burn. Well, all that we have had to pay for. I have told you that we have made all these installations, and you must understand from what I have said, that we have paid our expenses, that we have made some money out of some one. We have to speak of the chief work, lighted up the town of Cleethorpe, a place in one of our districts, and we have done it very successfully. That is the arc light, and arc lighting is our profitable business. The incandescent light does not appear yet to be sufficiently perfected to justify going out of your way to beg for business. You must bear in mind that our district is mainly one of factories, and where we get the power supplied a manufacturer can afford to put up the light much cheaper than if he had to put up the machinery. As I say, we have lighted up Cleethorpe, and I think we shall there get some incandescent lighting. We have done very well indeed at Nottingham. We have put up an installation there in the factory of a firm very well known, who are so satisfied with it that they have invited their friends to go and see it. We have done the same thing for another large firm at Nottingham. At Lincoln we have done some very good business. We have also got the following contracts, which are either about to be settled or which we shall get; and I think when you listen to what I have to say you wil be rather astonished that our officials have done what they have. In Oxfordshire we have no fewer than five contracts ready, and we do not put up any light unless it pays us. At Nottingham we have four; at Leicester a most important one, which it will not be for the interest of the Company that I should mention; at Carnarvon one, at Chester one, at Cleethorpe we shall get a large quantity of work, at Stockport one, at

Digitized by Google

Fordingham one, and at Leicester two. You must not forget that every installation we put up not only pays us but is also an advertisement. All these contracts I gave instructions to the manager myself were to await the decision of this meeting. If you choose to liquidate, all these contracts go to the wall; if you go on there is profit enough in my opinion to pay you a very fair dividend. If this time next year we should not be able to pay a dividend we should at least pay our expenses. I shall now read the resolution which we propose to pass, but which I shall not put immediately. It is as follows:—"That this meeting, having heard the statement of the chairman as to the position of the Company, is of opinion that the business of the Company should be continued, notwithstanding the proceedings of the shareholders who have demanded the return of their money; and therefore request the directors to arrange for the immediate withdrawal of the petition."

Mr. BEDFORD observed that the shareholders could not fail to have been gratified at what the chairman had stated concerning the progress of the Company. In compliance with the wish of the chairman, he referred, from personal observation, to the enormous progress in the United States since 1881 of the electric light, and particularly of the Brush arc light. The question was, was it a permanency? He could only say that the lights appeared to have been put up in a substantial manner, not on the old lampposts, but on regular lampposts for the purpose, something like 40ft. or 50ft. high. The gas lamps, too, had been dismantled. The price of gas had been reduced from 3 dols. to 2 dols. per 1,000 cubic feet.

The CHAIRMAN: I may inform the meeting that at Cleethorpe the gas company in a rage took up all the gas mains.

Mr. BRAITHWAITE could not but think that the shareholders should be rather glad than otherwise of the incident referred to which had enabled them to meet the directors, and hear the very satisfactory and frank statement of affairs that had been laid before them. When they looked at the position of the Company he thought they had every reason to be satisfied. They found that the patents which had been acquired by the Company gave them the exclusive use of the celebrated Brush dynamo machine over fourteen counties of England, and he ventured to say that a right like that to use the Brush dynamo machine, which, he said, was admitted on all hands to be the most efficient—was no trifle. As to the Lane-Fox incandescent lamp he had used it in his own house for three months, and had not broken a single lamp since he began their use. As to their not having the exclusive right to use it that was a play on the word. If the British Electric Light Company sold it at all they must, by their agreement, give it another name. He expressed his entire confidence in the future of the Company with its small capital of £60,000, including the call payable the next day. They were now doing a sound, remunerative, and increasing business, and he believed they had a good prospect of a dividend at no distant day.

Mr. STUART thought the principal question for the meeting to consider was, how the persons who were bringing the actions were to be met?

The CHAIRMAN: If the worst comes to the worst it is only a question of £250.

Mr. STUART: But others may follow.

The CHAIRMAN: I think not after the expression of this meeting.

Mr. STEWART thought that the question raised had nothing to do with the object for which the meeting had been convened.

Mr. BRAITHWAITE pointed out, as regarded the suggestion of other shareholders following the course taken by the 18 shareholders alluded to, that, if necessary, the shareholders could sign any circular sent round by the directors stating that they condoned the error in question.

The CHAIRMAN then put the motion, and declared it carried with one dissentient—a gentleman who stated that he held 10 shares.

On the motion of Mr. W. PAYTON, a vote of thanks to the chairman was passed, and the meeting separated.

YORKSHIRE BRUSH ELECTRIC LIGHT AND POWER COMPANY (LIMITED).

A special general meeting of the shareholders in this Company was held at the Cannon-street Hotel, on the 15th inst.

Mr. H. W. LOWE presided, and stated that the meeting was one of the greatest importance—in fact, they had to decide on a matter of no less interest than the continued existence of the Company or its immediate dissolution. In view of the recent action of one of the shareholders the Board decided to convene that meeting at the earliest practicable date, that the shareholders might attend and receive a full explanation as to the affairs of the Company. He had first to call attention to the circular issued by Mr. Charles P. Whiteley, and denied the accusations it contained. The directors did not proceed to allotment till 36,632 shares had been duly applied for and the money paid into their bankers. In his second circular Mr. Whiteley asked the directors to deny if they could that they had held meetings with the directors of some of the other incriminated companies over this business, or that they had met the Hammond Company and tried to get concessions from them as compensation for the blunder. Well, he was glad to say that the directors had not, either individually or collectively, been present at any such meeting, nor had they had the slightest intercourse with any representative of any other company. He also denied most emphatically that they had had any meeting with the Hammond Company or tried to get any concessions from them of any kind. At the earliest meeting of the Company the directors read over the two licenses very carefully, and no one ever entertained the slightest idea that there was anything in them but that they were intended to be exclusive licenses granted to them. The language of the licenses appeared then, and did so now, to the directors to be direct and exclusive, and he must point to the several other companies in proof that the directors of this Company were not alone in that view. Not one word was ever heard of any doubt or question on this subject until Sir Charles Bright wrote, on the 3rd October, and pointed out that there was a concurrent license granted to the British Electric Light Company. He desired to say nothing which could interfere with any legal rights they might have against the Brush or the Hammond Company for any compensation, but he was frank to admit that they had not so lost one farthing. They had no fear of loss from the competition of the British Company in Yorkshire, but if so he ventured to assert that the Lane-Fox lamp, as now made by the Brush Company and sold to this Company by the Hammond Company, owing to the improvements made in it, was of infinitely greater power than the lamp to which the concurrent license applied, and the British Company had no power to get from the Brush Company this splendid improved Lane-Fox lamp. They were now just completing the installation at Middlesbrough of the forty lights that were worked on the rental system; and he felt sure from the promises they had received that that work would be repeated to the same extent. They had given up the idea of exhibiting or doing any work for nothing; they declined all work which did not give them a profit. They were negotiating also for an extensive amount of work, and they expected to get as much as would keep them at work. Their expenses were kept down to a very low point; they had no preliminary expenses to write off, and they began with a clean sheet. Even if they did not make sufficient to pay a dividend at the end of the year they would show that they had not been wasting money. At present they had to oppose the enormous monopoly of the gas interest, and they could not expect with a novelty like the electric light that its progress would be at once rapid; it must, in fact, be gradual. The directors considered that the Company was making fair and satisfactory progress, and at no great expense. The prominent question was, should the Company at the wish of a few discontented shareholders, and at the instigation of one of them, be wound up and cast adrift? Adding the enormous charges of the lawyers and liquidators, and the usual expenses of winding up, nothing could be left but the ashes for the shareholders. He had no other interest but to make the Company a success. He would, before submitting the resolution he intended to move, ask Mr. Phillips, their consulting electrician, to give them some practical explanation as to the Lane-Fox lamp.

Mr. PHILLIPS accordingly proceeded to explain the nature of the original Lane-Fox lamp, and the improvements which had been made in it. He stated that the lamp they had now was as different from the former lamp as could be imagined. The cost was considerably less, no doubt, and would be rendered still cheaper: and it could be better made and sold at a profit at 3s. or 4s. than the former at 6s. or 8s. They could, too, fit it now for 1s. or 1s. 6d., instead of 10s., and it could be sold throughout Yorkshire at a handsome profit of 4s. or 4s. 6d.

The CHAIRMAN then moved: "That this meeting hereby empowers the directors to carry on the business of the Company and to oppose the winding-up petition lodged by Mr. Whiteley, and to take such steps as they may deem necessary for the protection of the Company's interest."

Mr. BROUGHAM, in seconding the motion, expressed his regret that such charges had been brought against the directors, who were gentlemen of high character and well known.

Mr. WHITELEY said that the chairman admitted that the directors thought when they bought the concessions that the licenses for the Lane-Fox lamp were exclusive, and that admission had proved his case. The directors, however, said that though the licenses were not "exclusive" they were "full," that that was about the same thing, and that the Company had not been damaged. He maintained that that was a most improper position to take up. He could believe that no damage had been done so far, but what was there on the credit side? He was not prepared to press criminal charges against the directors, or to charge them with dishonourable conduct. He defended the position he had taken up, and stated that he had none but perfectly honest intentions. Turning to the prospectus he made several references to and quotations from it with the view of showing that the shareholders had been induced to subscribe their money on misleading statements. It was, for instance, stated that allotment would not be made unless 35,000 shares were *bonâ fide* subscribed by the public. He contended that nothing like that number had been subscribed for. There were, therefore, 11,633 shares left. The chairman had suggested that he had taken isolated action, but he had 101 shareholders behind him, representing 2,949 shares. He contended that he had shown that they had been grossly misled—he did not say by the directors, but it was to the directors they looked. He had read Mr. Hammond's statement as to the Ferranti machine, and he inquired if that meant that that machine was going to supersede the Brush machine. If so, what had they paid their money for? Supposing that £2 a share had been paid on the 61,633 shares there was a capital of £123,266, of which, according to the prospectus, £100,000 was to be paid for the concessions. That left them, in the most favourable view of the case, with a capital of £23,266 to work an area described in the prospectus as one-ninth of the whole of England. It followed, too, naturally, that out of every £123 earned £100 would go to the promoters and £23 to the shareholders. What chance, therefore, was there of making this a successful Company? He asked the meeting for their support on these grounds, and ventured to assert, in conclusion, that even if the Company went on now it must fail eventually.

Mr. H. B. SEELEY complained that the Company had been illegally formed, as the number of shares mentioned in the prospectus had not, he said, been subscribed for by the time fixed for closing the lists.

Mr. M'ALISTER supported Mr. Whiteley.

The CHAIRMAN, in reply, again denied that there had been any of the "furtive meetings" alluded to by Mr. Whiteley as regarded the directors of this Company. With regard to their not having the exclusive license to the Lane-Fox lamp—a fact which came on them entirely unawares—no one had raised the slightest question about their exclusive rights to the use of the Brush machine, and the word was exactly the same in both cases. They, however, wrote to the Hammond Company, requesting them to explain the circumstance. They received a reply, stating that the Hammond Company was in communication with the Brush Company on the subject, and they would answer the communication from this Company as soon as they heard from the Brush Company. Immediately after that came the petition to wind up the Company, and Mr. Whiteley's circular. The directors at once then decided to await the result of that meeting before proceeding further. He felt sure that the Hammond Company had always behaved most honourably to this Company and their other subsidiary companies, and he was certain there would be no difficulty in their meeting this case to the satisfaction of most of them, if not all of them. As far as they could learn the Hammond Company had been taken as much by surprise as any of them. If they had suffered any damage they might depend upon it that the directors would do all they could to rectify it.

Digitized by Google

The question of capital rested with the directors, who knew the kind of business they were going to undertake. If they had had £50,000 or £70,000 they would have had to bank it. They had paid nothing for the Lane-Fox license. The Brush Company, he said, must have known that they could not sell the lamp, and the Hammond Company sold this Company what they conceived they had bought from the Brush Company. He had now stated very frankly what the views of the directors were. So far they had sufficient capital for their requirements; and if they undertook any large work they had an arrangement with the Hammond Company by which that Company found the capital and this Company would have the profits.

The SOLICITOR (Mr. Ince), speaking as a shareholder, strongly urged the continuance of the business of the Company. After referring to the value of the concessions possessed by them, he condemned the action of the directors of the Anglo-American Brush Company in not stating that they held the Lane-Fox license concurrently with the British Company.

The CHAIRMAN put the motion and declared it carried.

Mr. WHITELEY then demanded a poll.

The CHAIRMAN stated that, according to the Articles of Association, the demand could not be acceded to unless it were made by seven shareholders, holding in the aggregate £5,000 in the capital of the Company.

The meeting then terminated, having lasted for nearly three hours.

DEVON AND CORNWALL ELECTRIC LIGHT AND POWER COMPANY (LIMITED).

An extraordinary general meeting of the shareholders of this Company was held at the City Terminus Hotel, on the 16th inst., "for the purpose of considering a statement which will be made by the directors of this Company, and of passing resolutions thereon." Mr. William Henry Owen presided.

The SECRETARY (Mr. F. B. Lidstone) having read the notice convening the meeting,

The CHAIRMAN read the circular which had been issued to the shareholders. It stated that the directors had been prepared for difficulties in the way of introducing the light to the public, but notwithstanding that they had used every endeavour to promote the business of the Company, they had hitherto met with little or no success. Reference was then made to their purchase of the concession granted by the Great Western Company of what the Devon Company was given to understand was, *inter alia*, the exclusive right to use the Lane-Fox lamp in Devon and Cornwall. It now appeared, however, that the vendors of the concession had no such exclusive right. Shareholders had commenced actions to recover the money they had subscribed on the ground of misrepresention in the prospectus, and one shareholder on the same ground had presented a petition for winding up the Company. The questions for consideration were (1) whether the Company should be wound up, (2) whether any, and, if so, what, steps should be taken to re-construct the Company, or whether the Company should be continued as heretofore. Continuing, the chairman said that he gave the Great Western Company credit for having been in ignorance of the error they were committing in selling to this Company that which they did not possess themselves. The directors of this Company could not have supposed that there was anything wrong, having regard to the statements placed before them by the Great Western Company and the statements published in the prospectus of the Company. He, however, thought that the Company had not been damaged by not having the exclusive right to use the Lane-Fox incandescent lamp, having regard to the requirements of the recently-passed Electric Lighting Bill, which would compel them to supply any lamp a consumer might require.

Mr. GILBERT TERRELL (solicitor), who, he said, spoke on behalf of clients representing half of the capital of the Company, contended that it would be suicidal to wind up placed as the Company was, as in that case the concession they had purchased would revert to the Great Western Company, and instead of £22,000 subscribed by the shareholders they would have divided among them about £3,000. What they had to do first was to see what steps they could take to recover the money they had paid. He doubted whether any shareholder would succeed in an action for the recovery of the money he had subscribed. He concluded by moving a resolution appointing a small committee to confer with the directors as to the management of the Company, to investigate its affairs, in particular as to the responsibility for statements contained in the prospectus of the Company, and to present a report seven days before the adjourned meeting to be held on December 23.

Mr. E. FEWINGS seconded the motion.

The CHAIRMAN stated, with regard to the question how the clause complained of could have crept into the prospectus of the Company, that no business man, after placing a matter in the hands of his solicitor, looked into the affair himself. The same solicitors—Messrs. Fussell, Pritchard, Swan, and Henderson (of Bristol)—acted for the Great Western Company and this Company—seller and buyer. He was prepared to admit that that was an irregular, though it was not an unknown proceeding. He, however, raised the question at the time, but it was of a delicate nature.

Mr. WALTER WEBB objected to the resolution. He argued that the shareholders should show the utmost confidence in the directors and so strengthen their hands.

Mr. HOWARD would oppose the appointment of a committee, and he held that they could pass no resolution whatever at that meeting.

Mr. SHEPPEY held that they should continue the business.

Lord CLAUD HAMILTON thoroughly concurred with Mr. Webb. To attempt to wind up the Company or place affairs in the hands of a committee would be suicidal. He was a director of the present Brush Company, who had sold concessions, acting, as they believed, in the interests of their shareholders. All that the present Company gave, however, was the exclusive concession for the Brush dynamo machine and arc light and a license for the full use of the Lane-Fox lamp. Knowing they could not give an exclusive right to the use of that lamp they gave a full right, making no charge for it. They sold concessions to those who wanted them, and any errors that had occurred were doubtless attributable to those who had been concerned in the formation of the sub-companies. He maintained that no fault was owing to the Brush Company. As to the practical result, however, he did not believe that 6d. loss had been sustained by the misuse of the word "exclusive." He believed that this storm in a teacup would soon be calmed. The directors should be strenuously supported.

Mr. HENRY MAUDSLAY, M. Inst. C.E., a director of this Company and of the Great Western Company, stated that the Board were under difficulties, and they asked for the co-operation of the shareholders. He thought that the Brush Company at the outset had made a great mistake in charging so largely for their articles. This he said was shown in the enormous decline in the market value of their shares. They were now acting differently. He himself had lost £4,000 by electricity, and he held 1,000 shares in this Company (£2 10s. paid), which were selling in the City at 3s. 6d. He had actually sold 100 shares in the Great Western Company (£2 10s. paid) for 10s. He then explained the circumstances of the formation of the Company, and said that the point to know was who were responsible. An investigation of the affair would not necessarily be for the winding-up of the Company. What the directors required now was the confidence of the shareholders. He admitted that the directors had committed an error.

In answer to Mr. COLLINS,

The CHAIRMAN gave an outline of the operations of the Company, with the view of showing that they would be justified in continuing the work.

Mr. TERRELL consented to withdraw his resolution, and,

At the suggestion of Mr. WEBB, a motion was submitted and approved—not as a resolution, but as an expression of the opinion of the meeting—giving its entire confidence to the Board, and desiring to strengthen its hands in continuing the business of the Company, and opposing all hostile actions against the Company, or the action thereof.

The proceedings then terminated.

SLIP

SOCIETY OF ARTS.—On Wednesday evening, Dec. 13, Mr. W. H. Preece, F.R.S., will read a paper before this Society on "Electrical Exhibitions."

TELEGRAPHIC EXTENSION IN QUEENSLAND.—The Postmaster-General of this colony has promised to construct a telegraph line from Rockhampton to Port Alma.

BRAZILIAN SUBMARINE TELEGRAPH COMPANY.—The traffic receipts of the Brazilian Submarine Telegraph Company for the week ended the 17th inst. amounted to £3,813.

ELECTRIC LIGHTING IN MELBOURNE.—The use of the electric light is becoming very general in many of the largest shops in Melbourne, says the *Colonies and India*.

ELECTRIC LIGHTING AT MAIDSTONE.—The Dog Show held at Maidstone last week was satisfactorily lighted up with Brush lamps by the South Eastern (Brush) Electric Light Company.

APPOINTMENT.—Mr. J. K. D. Mackenzie, A.S.T.E., has been appointed chief engineer and electrician to the Metropolitan (Brush) Electric Light and Power Company, of 110, Cannon-street, E.C.

LONDON PLATINO-BRAZILIAN TELEGRAPH COMPANY.—The revenue of this company for August is estimated at £1,694 (Western Brazilian portion £1,235, and land lines £459), against £1,813 in 1881.

EXHIBITION AT BUENOS AYRES.—According to the list of awards at this year's exhibition at Buenos Ayres, Messrs. Siemens Brothers have been awarded a gold medal for their exhibits under the head of electric lighting.

WEST INDIES.—The cable between St. Vincent and St. Lucia is repaired; that between St. Croix and Trinidad is now interrupted, and there is no telegraphic communication with Grenada, Trinidad, and British Guiana.

ROYAL SOCIETY.—At this society's meeting on Thursday last the following paper was to have been read by Mr. R. Shida, viz.:—"Experimental Determinations of Magnetic Susceptibility and of Maximum Magnetisation."

WEST INDIA AND PANAMA TELEGRAPH COMPANY.—The estimated traffic receipts of this company for the half-month ended the 15th November are £1,540, as compared with £2,129 in the corresponding period of 1881.

A POWDER MAGAZINE STRUCK BY LIGHTNING.—A despatch from Scutari, in Albania, dated November 17, stated that the powder magazine of the fortress at that place had been exploded by lightning. There was no loss of life.

ELECTRIC LIGHT IN LIVERPOOL.—The jewellery shop of Mr. W. L. Lawson, at 40, Lord-street, Liverpool, is now lighted by electric lamps. The lights are supplied by the Lancashire Maxim-Weston Company, of Peter's-lane, Liverpool.

ELECTRIC LIGHT IN PRINTING WORKS.—The Provincial Brush Electric Light Company have received orders to light up the extensive printing works of Messrs. Hazell, Watson, and Viney, at Aylesbury, throughout. Arc lamps will be used.

WESTERN AND BRAZILIAN TELEGRAPH COMPANY.—The traffic receipts of this company for the week ending November 17 were £2,548, after deducting the "fifth" of the gross receipts payable to the London Platino-Brazilian Telegraph Company.

LANCASHIRE MAXIM-WESTON COMPANY.—Mr. Thomas Ross Comyn has been appointed secretary for the Lancashire Maxim-Weston Electric Company, and the registered offices of the company have been removed to 56, New Broad-street, E.C.

ELECTRIC LIGHT FOR COLLIERIES.—The Hammond Electric Light Company have erected several Brush lamps at Birley collieries, near Sheffield, which are now in use. They are about to supplement these by a number of incandescent lamps also.

TELEPHONE WIRES IN BIRMINGHAM.—The Telephone Company in Birmingham are negotiating with the Corporation for the laying of some of their lines underground. The work will be begun by placing underground the wires now crossing Stephenson-place.

LIFE OF A MAXIM LAMP. -At the New York Post Office it has been found that the average life of a Maxim incandescent lamp (the ordinary 50 candle-power type) is nearly 1,900 hours. About 25 per cent. of the lamps in this office have burnt between 3,000 and 4,000 hours.

DIRECT SPANISH TELEGRAPH COMPANY.—This company have removed their general offices to Leadenhall-buildings, Leadenhall-street, E.C. The offices for collection, transmission, and delivery of telegrams are at No. 1, Leadenhall-street (corner of Gracechurch-street), E.C.

ELECTRIC LIGHTS IN MINES.—Electric lights are being fitted at some of the principal mines in the Furness district. Lamps are placed at an elevation over the pit heads. At Messrs. Kennedy Brothers' Ronheal Mines, the offices, workshops, and stores are illuminated by this means.

WEST COAST OF AMERICA TELEGRAPH.—The rate for messages, *viâ* Galveston and the Central and South American and West Coast of America Telegraph Company's lines, to Buenos Ayres has been fixed at 16s. 4d. per word, and to all other places in the Argentine Republic at 16s. 9d. per word.

ELECTRIC LIGHTING IN GHENT (BELGIUM).—The Edison Company in Belgium have fitted 60 incandescent lamps in the offices and works of Messrs. De Smedt and d'Hanis in Ghent. They are said to work well, and to cost less than the gas hitherto burned. Our readers must remember, however, that gas on the Continent is very dear.

ELECTRIC LIGHT ON SHIPS.—The "Malabar," Indian troopship, which is undergoing extensive overhaul and repairs at Portsmouth, is to be lighted by the electric light. The Edison incandescent system is the one selected, and the installation will be undertaken by the contractors. Each deck will be illuminated by A and B lamps.

ELECTRIC LIGHT IN COAL MINES.—Mr. Ellis Lever has offered to give a premium of £500 to any person who will invent the best portable electric lamp for use in coal mines. Mr. Burt, M.P., and Mr. W. Crawford have put themselves in communication with Mr. Lever for the purpose of rendering him their assistance in promoting the object he has in view.

DEATH.—The death is announced of Mr. Thos. B. Ascough, Postal Telegraph Department, on the 19th inst. Mr. Ascough was in the service of the Universal Private Telegraph Company previous to his transfer to that of the Post Office, and he continued to take a prominent part in the management of privates wires to the time of his decease, which occurred very suddenly.

ELECTRIC LIGHTING IN COLCHESTER.—The Corporation of Colchester have passed a resolution granting permission to

Digitized by Google

the South Eastern (Brush) Electric Light Company to break up the streets, in order to lay their cables. The company are making preparations for lighting the High-street, Colchester, with Lane-Fox incandescent lamps, and the work will be carried out as soon as possible.

Electric Lighting in Offices.—The offices of the South Eastern and Provincial Brush Electric Light Companies at 110, Cannon-street, E.C., are both lighted by Lane-Fox incandescent lamps. The current is supplied on the B.T.K. system of storage recently introduced by these companies, and which we illustrated and described in our issue of October 28. (*Elec.*, Vol. IX., p. 560.)

To be Wound Up.—A petition for the winding up of the Great Western Electric Light and Power Company came before Mr. Justice Chitty on Saturday last. It was presented by Mr. W. H. Budgett, a merchant of Bristol, and a shareholder in the company. The Electric Gas Lighting Company and the London and Provincial Electric Gas Lighting Company are also to be wound up.

Electric Lighting in Spain.—The Anglo-Spanish (Brush) Electric Light Company will shortly have an installation of Brush lamps running in Valladolid. The authorities of San Sebastian, where this company have been lighting several streets with similar lamps for the past three months, are so satisfied with the performances of the system that they have taken over the plant and are running it themselves.

Electric Light in Dundee.—Commercial-street, Dundee, is now lighted by five Brush lamps. The lighting is, by arrangement with the Police Commissioners, to last over one month as an experiment. The work of erecting the lamps, &c., was superintended by Mr. W. C. Martin, district electrician and manager of the Brush Company in Scotland. One of Robey's vertical engines is used to drive the dynamo machine.

Electric Lighting in Brixton.—The Standard Fyfe-Main Electric Light Company have received an order from the proprietors of the Bon Marché at Brixton to light up a portion of their extensive premises by means of twenty-four Fyfe-Main arc lamps similar to those that have been for some time in use at the *Daily Telegraph* offices in Fleet-street. The patentees claim for these lamps a power of 3,000 candles.

Lightning and Telephone Wires.—A continental paper, entitled *L'Europe*, says, with reference to the recent thunderstorms which have occurred throughout the whole of Europe, that, contrary to the opinion of some, telephone wires have in no case been a source of danger. At Brussels, Ghent, Antwerp, and elsewhere, where lightning fell with disastrous effects, the telephone lines remained intact. At Berlin again not a wire was damaged.

Electric Light at Bridgeton (Scotland).—One of Akester's patent arc lamps has been erected by the Universal Electric Company at Bridgeton Cross. Professor Jamieson, of the Glasgow College of Science and Arts, and Professor Silvanus P. Thompson, of Bristol University, are quoted as authorities for the statement that the lamp gives an illuminating power equal to 1,500 English standard candles per electrical horse-power expended.

Electric Lighting in Picture Galleries.—The Société Industrielle Belge d'Electricité has lighted up M. Vereschagin's exhibition of pictures at the Palais des Beaux Arts, Brussels, by means of 16 soleil or sun lamps. The pictures are placed in two rooms of 30 metres length each. In one of these rooms there are seven lamps, in the other six. The light is reflected on to the pictures, and is said to show them up most effectively, bringing out the colours very satisfactorily.

Electric Lighting at Kew.—The roads on the Selwyn Court Estate, between Kew and Richmond, are now lighted by Brush lamps. This estate has been divided into building lots, so that the roads will presently become streets. The South Eastern Brush Electric Light Company, who have carried out the above lighting by arc lamps, are also going to introduce incandescent lamps into the houses already built, and those about to be built. The current will be supplied on the B. T. K. system.

The Ferranti Machine.—As a good deal has been said about this dynamo machine lately, and as the most conflicting rumours are abroad concerning it, we may say that we have the best authority for stating that a Ferranti machine has been run recently with satisfactory results, and that experiments as to its efficiency, &c., are being conducted. We shall hope to be able at no distant date to publish some figures relating to these experiments, and to give some account of the machine.

Electric Light in Engineering Works.—The sixteen Brush lamps that have been in use for some little time at Hawthorn's engineering works at St. Peter's, near Newcastle-on-Tyne, have been increased to thirty-two. Messrs. Leslie, of Hebburn, who have also been using sixteen Brush lamps for some time, have had twenty-four more erected in their works, making forty lamps altogether. The plant in both cases has been supplied and erected by the Hammond Electric Light and Power Company, of Cannon-street, E.C.

Electric Intercommunication on Trains.—A good illustration of the need of this mode of intercommunication between passengers and guards was afforded on a German railway the other day whilst travelling between Lottringhausen and Hörde Stations, near Dortmund, in Westphalia. A fire broke out in a carriage of the train, the fire increased as the train progressed, and it was only by dint of much shouting that the unfortunate passengers at length attracted the attention of the guard, and were released from their perilous position.

Electric Light on a Yacht.—The new steam yacht, "Empress," recently built by Earle's Engineering and Shipbuilding Company, of Hull, and now being fitted up, will be lighted by incandescent lamps. Thirty Swans will be used, the current being supplied by a Bürgin dynamo, driven by one of Marshall and Co.'s $2\frac{1}{2}$ horse-power vertical engines. Accumulators will be provided, which will supply sufficient current to keep the lamps alight when the yacht is in harbour and the fires down. The work will be carried out and the plant supplied by Messrs. R. E. Crompton and Co.

A New Electrical Paper.—We have received a copy of *L'Elettricita*, a new paper, devoted to electrical subjects and published at Milan. The first number contains a portrait and memoir of Alexander Volta, a description of the telephone, an article on the applications of electricity, &c., and concludes with an article on electrical navigation. We notice a sentence in this article which is rather amusing. The writer is talking of steam yachts, which he says are now owned by numbers of "milord Inglesi, lords scozzesi, nobile yankees e principi russi." *L'Elettricita* begins with eight pages and an outside sheet.

Electric Lighting in a Cotton Mill.—The Kingston Cotton Mills, of Messrs. Wright, Turner, and Sons, at Pendleton, employing 700 hands, are now lighted up by the Edison system. At present two K dynamos only are running,

Digitized by Google

these being capable of supplying current for 500 incandescent lamps of 16 candle-power; but eventually it is in contemplation to run 1,000 lamps. Two Siemens arc lamps are used to light the mill yard. The actual number of incandescent lamps in use is 540. The work has been carried out by the Edison Company, of Manchester, under the superintendence of their engineer, Mr. Ruddle.

Professor Palmieri.—The death is announced of Signor Luigi Palmieri, well known in connection with the observatory on Mount Vesuvius. Although better known as an observer of earthquake phenomena, Professor Palmieri was not unknown in the electrical world. *L'Electricité* says that we owe a simple form of electrometer to him, constructed on the same principle as that of Pelletier. He applied his instrument to the construction of an original apparatus, designed to discover the frauds perpetrated by the vendors of olive oil in Italy. M. Palmieri, our contemporary says, had peculiar ideas as to the production of electricity. He thought that the condensation of the vapour of water disengaged large quantities of it.

Magnetic Observations.—A series of magnetic observations, which are to extend over the space of fourteen months, have recently been commenced at Goettingen, Germany. They will take place under the supervision of the Professor of the University on the 1st and 15th of every month, at the same hours as those performed by the international expeditions sent out to the North and South Poles. Their principal object is to ascertain the magnetic condition of the earth. Experiments will also be made with respect to magnetic intensity in the garden of the observatory, in a pavilion built up of wood and brick only, iron being omitted on account of the disturbing influences which it would exert, rendering the observations practically valueless.

Electric Light in Factories.—A portion of the lace finishing works of Messrs. Copestake, Hughes, Crampton, and Co., at Nottingham, have for some time past been lighted by 16 Brush lamps. The light given by this system has been so much appreciated by the *employés* and the firm that they have determined to introduce incandescent lamps into their rooms as well. Between 100 and 200 Swan lamps will, therefore, shortly be fitted up. The work required to be done by the hands is very fine and necessitates plenty of light, which must also be of good quality. The change from gas to electric light, so far as it has been tried at present, has been a great boon to the workpeople, affording, as it does, a purer atmosphere for them to work in. The lamps and machinery have been erected by the Hammond Electric Light and Power Company.

Transmission of Power to a Distance.—In a note on the subject of M. Marcel Deprez's experiments at Munich, our contemporary, *La Révue Industrielle*, says:—"The return of 60 per cent. quoted by M. Deprez (see *Electrician* of Nov. 4th, p. 589) was purely electrical, whilst the useful (*industriel*) return, that is to say the ratio, of useful work (measured on the brake at Munich) to work expended (measured on the dynamometer at Miesbach) was 30 per cent. at the most, or barely a half. The result, therefore, as announced to M. Deprez by the Committee at Munich, is that the 'electrical return measured varied from 50 to 60 per cent., whilst the useful return (*rendement industriel*) ranged from 25 per cent. in the first experiment (the generator making 1,000 revolutions) to more than 35 per cent. in the second one (the generator making 2,000 revolutions).'"

Provisional Orders.—The Provincial (Brush) Electric Light Company have given notice of their intention to apply for powers to supply electricity for lighting and other purposes in the following towns:—Bury St. Edmunds (Suffolk), Norwich, Luton (Beds.), High Wycombe (Bucks.), Lowestoft (Suffolk), Great Yarmouth (Norfolk and Suffolk), Bedford, Cambridge, and Ipswich. The SouthEastern (Brush) Electric Light Company have given similar notices with reference to Gravesend, Folkestone, Maidstone, Canterbury, Margate, Rochester, and Chatham, all in the county of Kent; Richmond and Croydon, in Surrey; and Colchester, in Essex. The Corporations of Warrington and Heywood, in Lancashire, and Swansea, in Glamorganshire, have also given similar notices as regards their boroughs. The notice of the Heywood Corporation refers, however, to powers to provide and maintain telegraphic and telephonic communication, in addition to electric lighting, &c. The Southend (Essex) Local Board have likewise given notice that they will apply for a provisional order.

The Telegraph in France.—The *Standard's* Paris correspondent wrote on Monday last as follows:—"An ill-considered attempt by a Radical member, M. Maret, to reduce the estimates for the Post and Telegraph Department, which M. Cochery has converted from a burden into a source of revenue, was defeated by the huge majority of four hundred and fifty-six to fourteen. M. Cochery is the Rowland Hill of France, and something more. M. Cochery, since he took in hand the management of the Postal and Telegraphic Service, has worked wonders. He has reduced the tariff for inland telegrams to five centimes (one halfpenny) per word, and that he has not effected equal reductions in the international tariff is solely due to the fact that his hands were tied by previous treaties and monopolies. It is due to him that telegraphic communication in France is cheaper and more rapid than it is in England or the United States. All who are compelled to use frequently the Postal and Telegraph Service, and who remember what it used to be, feel bound to acknowledge how much they are indebted to M. Cochery for facilitating their work. The estimates were carried *nem. con.*"

Electric Lighting on the Stage.—It appears that the letter from "A. I. C. E." to *The Times*, in which the writer descanted on the danger of allowing ballet girls to carry about electric lamps attached to their person, and which we noticed on page 4 of our last issue, was prompted by a paragraph, stating that the chorus ladies at the Savoy Theatre, who are to represent fairies in a new opera which is to be brought out there, are to wear Swan incandescent lamps in their hair. The conducting wires are to be covered with silk of the same colour as the ladies' dresses in order to render them less conspicuous. "A. I. C. E." is allowed by *The Times* to take his text from this subject, and preach a sermon on the iniquity of allowing theatrical managers thus to trifle with the lives of their "supers." We have no hesitation in saying that the danger incurred by the chorus ladies in question is so infinitesimal as practically to amount to none at all. "A. I. C. E." ought to know this, if he knows anything about electric lighting. If he does not, then he ought not to rush into print and talk nonsense. Above all, how is it *The Times* finds a place for such letters as that from "A.I.C.E?" We have referred to this matter in our leading article.

The Danger of Overhead Wires Illustrated.—A daily paper of Saturday last says:—"The dangers attending the fixing of telegraph and telephone wires on the top of buildings was yesterday (Friday) demonstrated in Manchester in an alarming manner. Shortly after one o'clock the large warehouse of Messrs. George Hodgkinson and Sons, quilt and counterpane manufacturers and packers, at Manchester, was totally destroyed

Digitized by Google

by fire, and a loss of probably £100,000 incurred. The warehouse was in the centre of the business portion of Manchester, and, with the exception of the Royal Exchange, was the most important centre of overhead wires in the city. Fully 300 wires converged on the building or passed over it, and were in the midst of the fire. A few of them broke soon after the fire had heated them, and fell into the street. The main portion held out until the roof of the warehouse fell in, and they were then broken by hundreds, and the ends of most of them fell in a state of white heat into the streets or on to the roofs of the adjoining buildings. The whole of the telegraphic and telephonic communication with the most important portion of the city was absolutely destroyed. The Mayor of Manchester (Mr. Alderman Hopkinson) and the chief officials of the Lancashire and Cheshire Telephonic Company and the Postal and other telegraphic companies were present at the fire immediately afterwards, considering the best means of restoring the communication; but some considerable time must elapse before that can be done. The hanging wires were a source of great danger for the time being. An agitation has been progressing for some time in favour of the Corporation compelling all electric communication to be made by underground wires."

Legal—The Telephone Case.—In the High Court of Justice, Chancery Division, on the 17th inst., before Mr. Justice Fry, the case of the United Telephone Company *v.* Orme and Co. came on again. This was an action for infringement of the Bell patents, but on the delivery of the statement of claim the defendants consented to judgment being given against them on certain terms agreed upon.—Mr. Moulton appeared for the company.—Mr. Williamson had been instructed by the defendants to express great regret for the infringement, to apologise to the plaintiffs, and to express gratitude for the generous leniency shown to them by the arrangement made.—Judgment was accordingly given against the defendants by consent.—On the same day the cases of the United Company *v.* Butler, and the same *v.* Haines, also came on. The first of these two actions had reference also to the Bell instruments. The defendant had been served with notice, but did not appear.—Mr. Justice Fry granted an injunction, with costs, in the terms of the relief prayed, ordered the defendant to deliver up all telephones and telephonic apparatus in his possession which infringed the patents, and directed an inquiry as to damages. The second was a similar case, with the exception that it sought to restrain the infringement of Edison's instruments, as to which, in the action against Harrison Cox-Walker and Company, his lordship, while holding that the claim with regard to the telephone was good, felt himself precluded from giving judgment for the plaintiffs upon it because of their failure to make good their case in regard to the phonograph That part of the claim rejected by the judgment, so far as the Edison instruments were concerned, had, however, been since got rid of by disclaimer, and his lordship now made a similar order to that made in Butler's case, except that it applied to both patents.

Local Authorities and the Electric Lighting Act.—The following resolution was passed at an adjourned conference of local authorities, held at the Grand Hotel, Birmingham, last week:—"After hearing the report of the deputation to the Board of Trade, and considering the position of local authorities both as regards the interest of the ratepayers in the event of such authorities themselves working the electric light, and in the event of its being worked by trading companies, this conference is of opinion that the science of lighting by electricity is not yet sufficiently developed to justify local authorities expending the ratepayers' moneys in becoming undertakers for the supply of the light; but that every facility should be given by local authorities to trading companies to enable them to develop and work the discovery, and that local authorities should content themselves by making proper provisions for the protection of the ratepayers in regard to the following, amongst other points:—1. Retaining full control of the streets. 2. Suitable situation of the works, so as to secure freedom from danger, nuisance, or annoyance to the inhabitants in the immediate neighbourhood. 3. Regulations as to the wires and lamps, so as to secure freedom from danger. 4. Supply at reasonable prices. 5. The right of purchase by the authorities from the undertakers at a shorter period, if possible, than that provided for by the Act. 6. To endeavour to limit the area over which provisional orders are granted, so as to confine it within such reasonable limits as will enable the local authority to purchase the undertaking with facility, and not have cast upon the ratepayers the burden of purchasing the monopoly over a large and extended area, and also so as to permit co-existent experiments to be made by other companies in other parts of the districts, providing an authority decides to concur in the grant of provisional orders to competing companies. 7. To secure from time to time on the board of management of the electric lighting company direct representation for the ratepayers, by stipulating that at least two members of the local authority shall be *ex-officio* members of such board of management."

Electric Lighting in the Country.—The Association of Municipal Corporations held a meeting a few days since, and came to the conclusion that it was expedient that corporations should take a general course of action with reference to the proceedings under the Act. The Corporation of Oldham, having sought the advice of Mr. Shoolbred, electrical engineer, this gentleman recommended them to select a small district in which to make an experimental trial of incandescent lighting. A district has been selected in accordance with this recommendation, and Mr. Shoolbred has been instructed to make an inspection thereof, and report on the probable cost of erecting and laying down the plant. It is intended, we believe, to begin with about 10,000 incandescent lamps. Batley (Yorks.) Town Council have resolved to apply for a provisional order. Leamington (Warwick) Town Council have adopted a similar course, and in making a recent contract with the gas company reserved the right to light by means of electricity three of the principal streets in the town. Aston (Birmingham) Local Board will not apply for a provisional order, but will open negotiations with one or more electric light companies to supply electricity for lighting purposes, the board retaining full control of the streets, &c. Birkenhead Town Council will apply for an order, and do not seem to look with a favourable eye on outside companies. Darlington Town Council own the gasworks, and consequently do not like other light supplying companies in the town. They will, therefore, apply for an order. Saltley (near Birmingham) Local Board, like Aston, will not apply for an order themselves, as they do not think that the ratepayers' money should be spent in "becoming undertakers for the supply of electric light." They, will, however, give every facility to electric light companies, proper regulations being introduced with regard to breaking up streets, &c. Balsall Heath Local Board (also near Birmingham) are of the same mind as Saltley and Aston. The Leek (Staffs.) Improvement Commissioners will not commit themselves to any course at present, but will "watch the progress of events." Tunstall

Digitized by Google

(Staffs.) Local Board will apply for an order, and oppose outside companies. The Wednesbury (Staffs.) Local Board have agreed "to leave the lighting of the town to private enterprise."

THE TELEPHONE IN FRANCE.—The following are some telephonic statistics for the week ending November 15 last, issued by the Société Générale des Téléphones of Paris:—The number of subscribers to the Paris exchange of this company on November 8 was 2,521, during the week they gained 28 and lost 10, leaving them on the 15th with 2,539. On the same date in 1881 the number was 1,933. The number of subscribers connected up to the same exchange on November 8 was 2,275, 17 more were connected up during the week ending November 15, and 11 were disconnected, leaving them with 2,281 subscribers connected up, the number at same date in 1881 being 1,330. The exchange has 152 auxiliary lines, consequently the total number of their lines on November 15 was 2,433. The number of direct communications between subscribers was 63,362, by auxiliary lines 56,392, making a total of 119,794. During the corresponding week of 1881 the figures were 98,717. In Bordeaux on November 8 the company had 233 subscribers. This was increased by 2 during the week, leaving them with 235 on the 15th inst., against 138 at the same date in 1881. On the same date they had 221 subscribers connected up, and 6 were connected during the week, making, on the 15th inst., 227, against 103 in 1881. The number of direct communications between subscribers was 4,505 during the week, against 825 in 1881, a marked increase. On November 8 the company's Havre exchange numbered 165 subscribers, against 99 in in 1881. On November 8 there were 151 subscribers connected up, against 68 last year. The total number of direct communications between subscribers to this exchange during the week ended the 15th inst. was 2,855, in 1881 it was 1,462. At Lille, the company had, on the 8th inst., 115 subscribers, against 32 in 1881. Of these, 86 were connected up on the 8th inst. The number of direct communications between subscribers was 825. At Lyons, on the same date, their subscribers numbered 374, and they gained 2 before the 15th inst., making the total 376. In 1881, it was 211. They had 345 subscribers connected up on the 8th, and on the 15th 347, against 174 last year. The number of direct communications between subscribers was 20,733, while at the same date in 1881 it was 7,726. The Marseilles exchange had 244 subscribers on the 8th inst. This was increased to 248 before the 15th inst., against 142 last year. Two hundred and thirty-one were connected up on the 8th, and 233 by the 15th, against 134 in 1881. The number of direct communications was 9,551, in 1881 it was 2,092. At the same date the Nantes exchange had 100 subscribers, and Rouen 52. Neither of these gained any during the week. Nantes had only 67 subscribers in 1881 and Rouen none. On the 8th inst. Nantes had 79 subscribers connected, and Rouen none. The number of direct communications at Nantes during the week was 1,116, against 821 in 1881. The total number of subscribers to the company's exchanges on November 8 was 3,804, they gained 36 during the week and lost 10, leaving them with 3,830, against 2,623 in 1881. The number connected up on November 8 was 2,388, 27 were added during the week, and 11 disconnected, leaving a total of 3,404 connected up, against 1,871 last year. The number of direct communications between subscribers over the company's lines during the week ended November 15 was 102,947, and by auxiliary lines 56,392, making a total of 159,339, against 71,643 in 1881.

ELECTRIC LIGHTING IN THE CITY.—On Tuesday last, at a special meeting of the City Commissioners of Sewers, held at Guildhall, Mr. Felton presiding, a report was brought up from the Streets Committee by Mr. Pannell, their chairman, in regard to the notices from various electric lighting companies of their intention to apply to the Board of Trade under the Act of 1882 to enable them to light the City by electricity. The committee instructed Colonel Heywood, the engineer, to obtain the opinion of some eminent electrician as to whether it would be practicable to lay in the same tube the conductors of various companies for lighting by different systems of electricity without the conductors so laid injuriously interfering with each other, and also whether the conductors laid in a district by any one company could, if their usage by that company be discontinued, be made available for any other company using a different system. They now submitted a long report from Mr. W. H. Preece, of the General Post Office, on these points. His opinion was that, except in a subway of considerable size, it was impracticable to maintain the conductors of different companies in the same tube. As to the other point, he observed that the arrangement of conductors to fulfil the requirements of an electric light system was a very complicated matter indeed, and he knew of no branch of engineering where more forethought was necessary to calculate all the contingencies likely to be met with than a system designed to illuminate a large city like London. Every system required its own distribution, dependent upon the area to be illuminated, the number of lights, the route of the conductors, and the position of the generating station. The whole question of the distribution of electricity for lighting purposes was in a very tentative state. Sufficient experience had not yet been gained to determine exactly what was required in all circumstances, or even what those circumstances would be, and he thought that those corporations who had taken on themselves to supply electricity had undertaken a responsibility that they had not sufficiently contemplated, and which, with the present state of our knowledge, was extremely difficult to discharge. Hence, he said, that while there might be cases where the conductors of one company might be available for another, there could not be a case where they were properly available unless the two companies employed the same system and utilised the same central station for the generation of their electricity and the distribution of their force.—Mr. J. V. Moore moved, and Mr. Boor seconded, "That the Remembrancer be instructed to take all necessary steps to enable the Commission to become the undertakers for the supply of electricity to the City under the provisions of the Electric Lighting Act, 1882; to obtain a provisional order under the regulations laid down by the Board of Trade, and to oppose the applications of all other parties." To that Mr. Innes moved, and Mr. Baptie seconded, as an amendment, "That while the Commission was in favour of electric lighting in the abstract, it was advisable to allow all further experiments to be conducted at the risk of the lighting companies, and not at the expense of the ratepayers." After a discussion lasting some hours, the amendment was carried by 31 votes to 26, and subsequently, on its becoming the substantive motion, by 22 votes to 21. It was then further resolved, at the instance of Mr. Alderman Staples, that the Remembrancer be instructed to appear, on the application of the electric lighting companies, and secure clauses protecting public and private rights. Mr. Stoneham gave notice of motion for the appointment of a Select Committee to inquire into the steps to be taken to enable the Commission to be the undertakers for the supply of electricity, looking at the vast interests at stake.

THEORY OF MAGNETO AND DYNAMO MACHINES.

XX.

E.M.F. Generated in a Modern Siemens Armature, made without Iron, and Rotating in a Uniform Magnetic Field.

Let each coil consist of K turns of wire, enclosing each a mean effective area A.

Let there be $2c$ such coils wound on the drum in pairs, as in Figs. 5—11 of the last article, the coils in each pair being close together, and the angles between successive pairs being $\frac{\pi}{c}$ or β.

Let the drum be rotated in a magnetic field, F, with angular velocity ϵ.

Then the E.M.F. in each coil at any time t is, see Art. XIV.,

$$K A F \epsilon \sin(\epsilon t + a)$$

where the phase a has values differing by β for successive coils.

The total E.M.F. in the armature is the sum of all the E.M.F.'s generated in the c coils in series, and is therefore

$$E = K A F \epsilon \{ \sin \epsilon t + \sin(\epsilon t + \beta) + \sin(\epsilon t + 2\beta) + \ldots\ldots + \sin\big(\epsilon t + (c-1)\beta\big) \}$$

$$= K A F \epsilon \frac{\cos(\epsilon t - \frac{1}{2}\beta)}{\sin \frac{1}{2}\beta} \quad \ldots\ldots\ldots \quad (1)$$

Now, if t is allowed to increase as much as it likes, this will represent a mere periodic function, which oscillates between the values $\pm \frac{K A F \epsilon}{\sin \frac{1}{2}\beta}$ in a period $\frac{2\pi}{\epsilon}$.

But then this is leaving altogether out of account the effect of the commutator, and it is just what would happen if the brushes of the machine rotated with the commutator so as always to rest on the same segment of it; or, what is easier to imagine, if the armature and brushes stood still while the magnetic field rotated.

But in the actual state of things the armature alone rotates, and it has only to turn through an angle β or $\frac{\pi}{c}$ for the brushes to rest on a new segment of the commutator, thereby making a fresh coil take the old one's place, and everything to start afresh.

This condition can easily be imposed upon the above formula by informing t that it can only be permitted to increase through $\frac{\beta}{\epsilon}$, and must then begin again at its former value, and so on.

This will cause the expression to be a quivering function of the time, with its variations exceedingly rapid, but almost insignificant in amount. It has its maximum value when $\epsilon t = \frac{1}{2}\beta$, and this maximum value is $K A F \epsilon \operatorname{cosec} \frac{1}{2}\beta$.

The brushes should be set so as to get the benefit of this maximum E M F, which they will do best if they are then touching the middle of a segment; and the variations in the current will then be less than if they are set in a less symmetrical position.

But now there is this very important thing to be noticed about these quiverings, viz., that unless the value of E, when the brush leaves one commutator segment, is the same as the value of E when it enters the next, there will be a discontinuity in the current and consequent sparking.

We saw in Art. XVIII. that with the Brush commutator there was always some sparking necessary, but this is not the case with the Siemens or Gramme machines; it may be possible in these so to set the brushes that the value of E with which they leave one pair of segments is the same as that with which they enter on the next.

Assuming that the brushes are always opposite to one another, but that instead of being set along the maximum line they are set an angle θ in advance, we shall have the initial E.M.F., when the brush first touches a segment, given by adding θ to the expression inside the brackets of (1), and by putting $\epsilon t = o$, or

$$E_1 = K A F \epsilon \frac{\cos(\theta - \frac{1}{2}\beta)}{\sin \frac{1}{2}\beta};$$

and the value when the brush leaves it, by putting $\epsilon t = \beta$,

$$E_2 = K A F \epsilon \frac{\cos(\theta + \frac{1}{2}\beta)}{\sin \frac{1}{2}\beta}.$$

Then when it enters on the next segment it becomes E_1 again, and so on; changing steadily down from E_1 to E_2 during the passage of a segment past the brush, but jumping suddenly up again from E_2 to E_1 as the brush crosses the gap to the next segment. And a jump like this is necessarily accompanied by extra current sparks, which waste power and burn the brushes and commutator. To avoid this discontinuity we must set the brushes so that $\theta = o$, *i.e.*, so that they are along the line giving the maximum E M F. Then putting $\epsilon t = 0$, we get the initial E.M.F. as a segment first reaches the brush, viz.:—

$$K A F \epsilon \cot \tfrac{1}{2}\beta \quad \ldots\ldots \quad (2)$$

This rises to a maximum as the brush comes on to the middle of a segment, viz., when $\epsilon t = \frac{1}{2}\beta$, being then—

$$K A F \epsilon \operatorname{cosec} \tfrac{1}{2}\beta \quad \ldots\ldots \quad (3)$$

and it then diminishes till the brush leaves the segment ($\epsilon t = \beta$), being then the same as it was at first, viz.:—

$$K A F \epsilon \cot \tfrac{1}{2}\beta,$$

and ready to pass on to the next segment without discontinuity or sparking.

Under these circumstances, therefore, the E.M.F. quivers between a maximum and a minimum value $2c$ times in a revolution, or $\frac{\epsilon}{\beta}$ times a second; the maximum value being inversely proportioned to the sine, and the minimum being inversely proportioned to the tangent, of the small angle $\frac{1}{2}\beta$ or $\frac{\pi}{2c}$. The ratio of the minimum to the maximum value is $\cos\frac{\pi}{2c}$, and remembering that c is the number of pairs of coils on the armature, and that this is seldom less than 12 or 16, while in the common Z Edison it is 72, we perceive that the variation is very small; and that it may in fact be neglected. We can, therefore, in all cases where c is reasonably large, write $\frac{2c}{\pi}$ instead of either cosec or cot $\frac{1}{2}\beta$; and so the E.M.F. is simply

$$E = \frac{2c}{\pi} K A F \epsilon,$$

or if the number of revolutions per second is n, and since $\epsilon = 2\pi n$,

$$E = 4 n c K A F \quad \ldots\ldots \quad (4).$$

Resistance of the Wire on the Armature.

The resistance of the armature may also be recorded. If r_1 is the resistance of unit length of wire used, and if the armature is μ times as long as it is broad, then since the current has to flow through c coils in series and 2 abreast, the length of each turn of wire being $2(\mu + 1)\sqrt{\left(\frac{A}{\mu}\right)}$, the resistance from brush to brush is

$$R = c K r_1 (\mu + 1) \sqrt{\left(\frac{A}{\mu}\right)} \quad \ldots \quad (5).$$

This shows that the best value of μ is 1, or that the armature ought to be as broad as long. It is, indeed, obvious that to get the greatest area with a given length of wire the best shape is a circular coil, and that the square is the best form of rectangle; nevertheless, it is frequently asserted that a Siemens armature should be long in proportion to its breadth, from some mistaken idea that the longitudinal portion of the coil is the useful, and the end wires the useless part. The real advantage of making the armature long and

Digitized by Google

narrow is to make the gap in the magnetic circuit (the distance between the pole pieces) as short as possible. Hence the more soft iron the armature contains, the squarer may its longitudinal section advantageously be.

Hypothetical Case.

It may be useful to take a numerical example of the E.M.F. and resistance of a suppositious armature. Let the commutator have 24 segments, the armature being wound with 12 pairs of coils. Let each coil consist of 10 strands of wire in series. Let the length of the armature be 16 inches, and its diameter be 8 inches, so that the mean effective area A is about 800 square centimetres if it contain no iron.

As to the strength of the field F, the earth would only give ·47, permanent magnets might easily make it 100 units strong, and with an electro-magnet it might be got up to 1,000. Let us suppose it is 1,000.

The speed we may put as 1,000 revolutions a minute, which will make $\epsilon = 105$.

The maximum value of the E.M.F. when the brushes rest on the middle of a segment is, by equation (3),

$$10 \times 800 \times 1{,}000 \times 105 \operatorname{cosec} \frac{\pi}{24} \text{ absolute units,}$$

or, as $\operatorname{cosec} \frac{\pi}{24} = \frac{1}{\sin 7^{\circ}\cdot 5} = 7\cdot 66$, and as 10^8 units $= 1$ volt,

$$\text{max. } E = 64\cdot 34 \text{ volts.}$$

The value of cot $7\frac{1}{2}$ is 7·60, and hence, if the brushes are properly set, the value of the E.M.F. as they enter or leave a segment is, by equation (2),

$$\text{min. } E = 63\cdot 84 \text{ volts,}$$

and it will have to oscillate from one of these values to the other and back again 24 times in a revolution, or 400 times a second. As a matter of fact this is almost too rapid for the above change, though it is but half a volt, to take place completely. Moreover, we have been assuming the magnetic field uniform, but if the poles are curved round the armature so as to make each coil cut the lines of force normally as far as it can, we shall get still further uniformity, and nearly all the coils will be more decidedly assisting the action; in other words, the semi-neutral region will be diminished.

To find the resistance of such an armature, suppose the wire on it is No. 14 B.W.G., which has a resistance of 1·5 ohm per 1,000 feet about, or 20,000 centimetres to the ohm, then, by equation (5),

$$R = \frac{12 \times 10 \times 3}{20{,}000} \sqrt{\left(\frac{800}{2}\right)} = \cdot 36 \text{ ohm.}$$

NOTE.—Fig. 12 of last article was intentionally erroneous, and it would have been better so to label it to avoid misunderstanding.

THE (ELECTRIC) CONDUCTIVE AND INDUCTIVE CIRCUITS GEOMETRICALLY ILLUSTRATED.

BY F. C. WEBB, M.I.C.E.

(CONTINUED FROM PAGE 522, VOL. IX.)

If the battery is entirely insulated, and has no wire connected to either pole, and is also equidistant at each part from surrounding objects, and could be so charged with its liquid that its electromotive force shall come into action without any part of the battery being even for an instant in communication with external objects, then the potential at one pole will be positive and of a potential equal to half the electromotive force of the whole battery, whilst the other pole will be negative and of a potential equal also to half the electromotive force of the battery. The figure will then take the form shown in Fig. 24, A B representing the axis or line of potential equal to zero.

If either pole be touched with any object that can become charged, that pole will lose electricity, and the datum line will move up or down, according to which pole is touched, but always towards such pole and parallel to itself. If one pole is touched to earth, then the datum line will pass through that pole. Thus, if the negative pole is touched to earth the figure will become as in Fig. 25, and if the positive pole is touched the reverse figure below the datum line will occur, the negative pole obtaining a negative potential equal to the whole electromotive force of the battery.

If two bodies of unequal electrostatic capacity are attached to the poles, then the datum line will adjust itself in such a

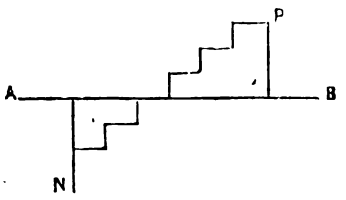

FIG. 24.

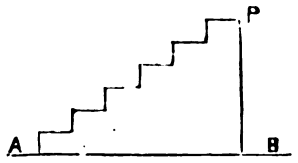

FIG. 25.

way that the quantities of electricity on each body and on a portion of the battery connected to it shall equal the quantity of electricity on the other body and on the remainder of the battery. Neglecting, for simplicity, the quantity on the battery itself, if we suppose two unequal lengths of submarine cable of similar pattern, with insulated ends attached to the two poles of a battery previously insulated at both poles before charging, then the datum line will so adjust itself that the two charges shall be equal in quantity, the length of one multiplied by the potential of the pole

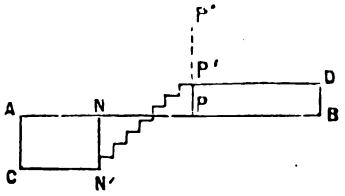

FIG. 26.

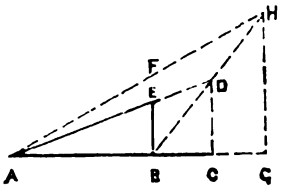

FIG. 27.

attached to it being equal to the length of the other multiplied by the potential of the pole attached to it.

Thus, if in Fig. 26, N P is resistance of battery and P P′ the electromotive force of the battery, then if a wire of equal electrostatic capacity per unit of section throughout and of a length represented by P B be attached to the positive pole P, and a length represented by A N of similar wire equal, say to half, P B, be attached to the negative pole, then the potential at P will sink to such a potential, P P″, and the negative potential at N to such a potential, N N″, that the

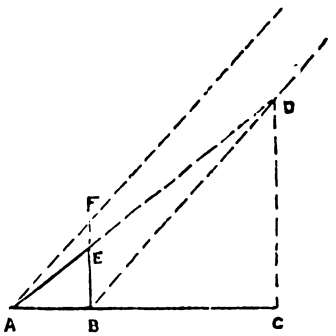

FIG. 28.

parallelogram A N N″ C, representing the charge in the wire A N, shall equal the parallelogram P P″ D B, representing the charge in the wire P B. I shall deal with the problem of insulated wires attached to the poles of an insulated battery again further on, when dealing with "inductive circuits," as there are some interesting facts connected with the subject which I have hitherto only briefly alluded to in a number of *The Electrician* some four years ago. Enough has now been given to show the general action, if I may use the term, which

Digitized by Google

takes place with a battery when either one or both poles are insulated.

Turning again to problems of current, electromotive force, and resistance in a circuit, let A B (Fig. 27) be the external resistance of a circuit to earth at A, B C the resistance of the battery to earth at C, and C D the electromotive force, then joining D E will give B E as the potential at the battery pole attached to the external resistance, and $\frac{B\,E}{A\,B}$ is the current. Suppose now we wish to increase the current in A B to one half as much again, and wish to see how to do it. Increasing potential at B to B F = $1\frac{1}{2}$ times B E, join A F and produce indefinitely. Join B D and produce it till, if it *converges* towards A F prolonged, it meets that line at H. Then dropping H C perpendicular to A B C prolonged until it cuts at G. Then B G will be the resistance of the new battery of similar elements to B C in terms of whatever number were contained in B C, which must be employed to produce the new current, and G H will be its electromotive force. Thus, if B C contained 10 elements and B G is 2·2 times B C, then the total number required will be 22.

If, however, the resistance of the external conductor A B is small compared to the resistance of the battery, then it may happen that the lines A F and B D may be parallel, indicating, as will be seen by Fig. 28, that no increase of the same elements in series can obtain the desired current. Or they may actually diverge, which would represent also that no increase of elements could obtain the desired current. Finally, they may converge, but so slightly that they will only meet after very great prolongation, which would show that an enormous increase of elements would be required in series to obtain the desired current. In such case the desired current can only be obtained by reducing the internal resistance of the battery.

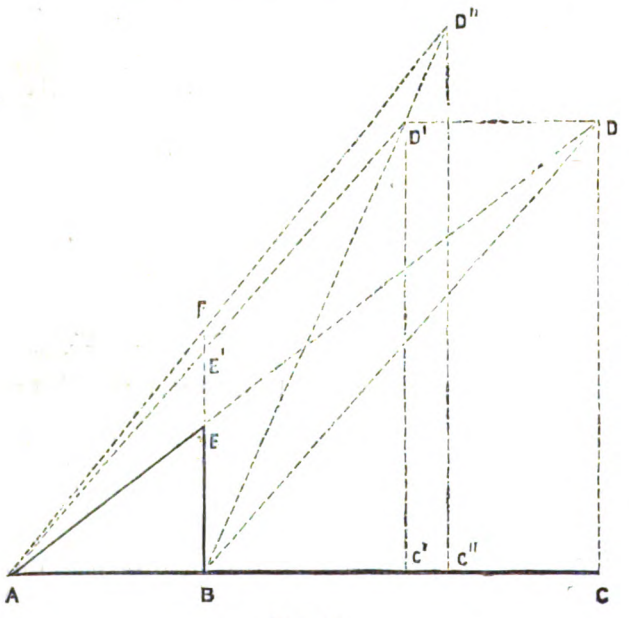

Fig. 29.

Thus, if A B (Fig. 29), as before, represent the external resistance, B C the battery resistance, and C D the electromotive force, it will be seen that A F produced and B D produced cannot meet, indicating that no increase of battery in series can produce the desired current. If we were to double the size of the plates or use the same number of double elements, the resistance of the battery would be halved whilst still preserving the same electromotive force as before, and, halving B C at C′ and making C′ D′ = C D, and joining D′ A, we should get A E′ as the line of potential. This falls within A F, and we have not yet, therefore, obtained our object. But now, joining B D′ and prolonging it till we cut A F prolonged at D″, and dropping the perpendicular D″ C″, we get B C″ as the resistance of the battery required, and consequently the number of the cells of reduced resistance in terms of whatever number were contained in B C′.

THE RELATIONS BETWEEN MAGNETIC FORCE AND ELECTRIC CURRENT.—II.

BY OLIVER HEAVISIDE.

In the preceding article bearing the above title, the meaning of the "curl" of a vector was explained and illustrated in the case of a steady current in a long straight wire. Also, from that solution were derived, by the operation of curling, the distributions of current corresponding to other possible arrangements of magnetic force. We now come to some other properties of magnetic force and current, and more generally of any similarly related vector quantities. To fix ideas, let B be a possible distribution of magnetic force, and C the corresponding electric current. We know that $C = \frac{1}{4\pi}$ curl B, and we may similarly find the curl of C, which we may call D. Thus,

$$\left.\begin{aligned} B &= \text{magnetic force, given.} \\ C &= \frac{1}{4\pi}\text{curl } B = \text{current} \\ D &= \text{curl } C \end{aligned}\right\} \text{deduced.}$$

Supposing, however, that it is the current distribution that is given, how shall we find the magnetic force? Considering the fundamental relation only, that by finding the line-integral of B once *round* any axis we get $4\pi \times$ current-component *along* that axis, if we reverse the operation we discover at once that it fails to work in a suitable manner. We do indeed know from the given value and direction of the current at a given place what the line-integral of magnetic force round it is, but that does not tell us the magnetic force at different points along the line of integration. Some other method is, therefore, wanted.

There are different ways of obtaining the magnetic force from the current. We shall commence with that one of them which has the advantage of telling us immediately in a great many cases the general nature of the magnetic force. This method is expressed in the following statement. The magnetic force is the vector-potential of the curl of the current. Here we introduce another conception, that of the potential of a vector quantity, and in order to render it intelligible, some explanation becomes necessary.

The meaning of potential in electrostatics is well known, therefore we need here merely remind the reader that the potential of a charge e at distance r therefrom is $\frac{e}{r}$, where we suppose e to be at a point, or, at least, within a very small space surrounding the point from which r is measured. It is the work that must be done to bring a unit charge from an infinite distance to the place considered. For the electric force is by definition $\frac{e}{r^2}$, and the work done in bringing a unit charge from distance r_2 to distance r_1 from e is mean force × distance

$$= \frac{e}{r_1 r_2} \times (r_2 - r_1) = \frac{e}{r_1} - \frac{e}{r_2};$$

and when the distance r_2 is infinite, the work becomes simply $\frac{e}{r_1}$. The potential of any system of free electricity is the sum of the potentials of the elementary charges into which it may be divided, and we may write it

$$\Sigma\frac{e}{r} = \frac{e_1}{r_1} + \frac{e_2}{r_2} + \frac{e_3}{r_3} + \ldots$$

$e_1, e_2, \ldots$ being the charges, and $r_1, r_2, \ldots$ their distances from the point where the potential is to be found. The electric force in any direction is the rate of decrease of the potential in that direction. But we may also consider it as the sum of the forces due to the elementary charges, or $\Sigma\frac{e}{r^2}$, where, however, we must, since force is a vector, not simply add the numerical values of the forces together, but make the proper allowance for their being in different directions; that is to say, we must find their resultant. This is

Digitized by Google

most conveniently expressed by saying that we find the vector sum of the separate forces.

Now, in finding the potential of a vector quantity, such as current, we add together the potentials of the elements into which the current-system may be divided, *i.e.*, we find $\Sigma \frac{C}{r}$, but we must do it exactly as in the last-mentioned case of electric force, find the vector sum. Free electricity is scalar or directionless, and so is its potential, therefore simple addition of the numerical values of the potentials of the elements gives the value of the whole potential, and there is nothing else to consider. But if, for example, one current-element, C, is directed from right to left, and another equal one from left to right, the sum of their potentials at a given point is the difference of their separate potentials, and is directed parallel to the greater.

In certain cases, however the process is simplified. In a straight current, for example, the current-elements all point the same way; the potential of any element, C, at a point distant r, is $\frac{C}{r}$ parallel to C; every element of the total potential is parallel to C, and so is the total potential, and its value is the scalar sum of the potentials of the elements. We should therefore find the potential exactly as for free electricity occupying the same space as the current, and then make it a vector by giving it direction parallel to the current. Thus the potential of a system of parallel straight currents at any point is a vector drawn from that point parallel to the current; and, in general, the potential of one vector-system is another vector-system. To distinguish it from ordinary scalar-potential it is called the vector-potential. In the same way as we represent systems of magnetic force or current by means of lines, we may represent their vector-potentials by systems of lines, the direction of a line showing that of the vector-potential, and the density of the lines its magnitude at any place.

Thus the lines of vector-potential of a straight current are straight lines parallel to it, closely packed in the wire and near it, and falling off in density as we recede from the wire, according to the logarithm of the distance.

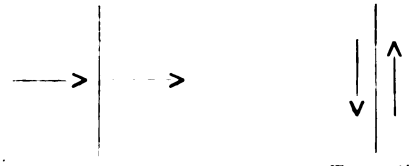
Consider next a circular current. It is easily seen, in the first place, that the vector-potential at any point, P, upon the axis of the circle is *nil*, for all the current-elements are equidistant from P, and for any element pointing one way there is just one other (at the opposite end of the diameter) pointing the other way, so that the vector-potential of one half of the circular current is annulled by that of the other half. Now, let P be no longer on the axis. It is, consequently, nearer one side of the circle than the other. The vector-potential of the nearer side preponderates, and the result is a vector at P drawn parallel to the nearest part of the circle. Let P describe a circle about the axis, parallel to the current; at every point of this circle, from symmetry, the same statement holds good, consequently the circle described by P is a line of vector-potential. Thus the lines of vector-potential of a circular current are parallel circles, centred upon the axis, closely packed in the current and close around it, and falling off in density both towards the axis in the neighbourhood of the circle, and away from it outside it.

If the current flows in a plane sheet, the current lines are closed curves in the sheet. The lines of vector-potential must be in planes parallel to the sheet, since there is no current perpendicular to it, and they are also closed curves.

In all cases we may find the vector-potential by means of three scalar sums instead of the vector sum; this is most conveniently done by forming the scalar sums of the components in three rectangular directions, and then compounding them. However convenient for calculations, this method often very much obscures the matter under consideration.

Now, we stated that the magnetic force was the vector-potential of the curl of the current. Take a straight current, for instance. As explained in the last article, the curl of the current is confined entirely to the surface of the wire, its strength is numerically equal to the current-density, and its direction is perpendicular to the current, so that the lines of the current-curl are equidistant circles on the surface, enclosing the current. From symmetry, together with the late remarks on the vector-potential of a circular current, we see that the vector-potential of the curl of the current is also in circles, in planes perpendicular to the axis, and centred thereon—that this must be the case both within and without the wire, and that they must be closely packed near the surface, and fall off in density both ways, *i.e.*, towards the axis within the wire, and from it outside. These characteristics will be readily recognised to be those of the magnetic force of a straight current.

Again, consider a current-system in a plane sheet, and derive the general nature of the magnetic force as far as we can. The current-density is supposed to be constant through the small thickness of the sheet, so that the current has no curl within the sheet and parallel thereto. But the current will in general vary from place to place in the plane of the sheet; it has, therefore, curl perpendicular to it, to be found by the line-integral of the current round a small area in its plane. This curl is a vector drawn perpendicular to the sheet, at some places it may be from the + side, at other places from the — side. Its vector-potential is the component of magnetic force perpendicular to the sheet, and we see immediately that it has the same strength and direction at corresponding points on opposite sides, and that it is continuous at the sheet itself. If *to* the sheet on one side, it is *from* the sheet at the nearest point on the other side. But besides this, there is the surface-curl of the current to be considered. As explained in the last article, it is got by turning the vector representing the current density through a right angle upon the surface. Since the sheet has two sides, we have two systems of surface-curl, both exactly alike, but oppositely directed. The lines of surface-curl intersect the current-lines at right angles. The vector-potential of this double system is the component of magnetic force parallel to the sheet. Now, on either side of the sheet, the nearer side preponderates over the other in contributing to the vector-potential, and since the surface-vectors only differ in being oppositely directed, it follows that the vector-potential is numerically the same at corresponding points on the + and — sides, but oppositely directed. Thus there is a remarkable difference between the components of magnetic force perpendicular and parallel to the sheet. The former is continuous, the latter discontinuous, as may be thus diagrammatically represented:—



Normal. Tangential.

Returning now to the general relations, it will be observed that whilst D, the curl of the current, is derived from B, the magnetic force by double curling (with division by 4π), on the other hand B is derived from D by finding its vector-potential. That is to say, the operation of finding the vector-potential is exactly annulled by double curling and division by 4π (the last operation being a question of units). Thus,

$$4\pi D = \text{curl curl potential } D.$$

This suggests that if we form a new vector, viz., the vector-potential of C, *its* curl will be the magnetic force. Thus, calling the new vector A, and at the same time introducing another vector E at the other end of the series, we have

A = vector-potential of C.

B = curl A = vector-potential of D = magnetic force.

$C = \frac{1}{4\pi}$ curl B = vector-potential of E = current.

D = curl C.

E = curl D.

Of the series, only B and C represent quantities having undoubted existence as physical realities; the rest are purely conceptions. But the last introduced quantity A,

Digitized by Google

the vector-potential of the current, is of as much importance in electro-magnetism as the potential of free electricity is in electrostatics, being in fact its exact counterpart. D is also very useful sometimes; the rest of the possible series up or down cannot be said to be more than curiosities. A is found from the current-distribution in an analogous manner to scalar potential from free electricity, only compounding the component parts like velocities, or taking the vector sum instead of the scalar sum. And as we derive electric force from the static potential by finding the direction in which the potential decreases fastest, and the rate of its decrease, the former giving the direction and the latter the magnitude of the electric force, so we derive magnetic force from the vector-potential of the current by curling, that is, by finding the direction of the axis round which the line integral of the vector-potential is greatest, and its amount, the first being the direction of the magnetic force, the second proportional to its magnitude. This is the most usual way in electro-magnetic investigations; it does not, however, usually give so much information without calculation as the method previously described, as may be illustrated in the case of a straight current.

If we have found the vector-potential of a current-system, we know the magnetic force, viz., its curl. But it is also the vector-potential of the curl of current, so we have—

$$B = \text{curl potential } C = \text{potential curl } C.$$

Thus the two operations of curling and finding the potential are reversible, or rather commutative. This putting the cart before the horse is a slight change only in words, yet makes a vast difference when we come to carry it out, although the final result is the same.

From this commutative property we have—

$$\begin{aligned} 4\pi C &= \text{curl curl potential } C \\ &= \text{curl potential curl } C \\ &= \text{potential curl curl } C = \text{potential } E. \end{aligned}$$

As may be seen from the last list, the whole series from A to E is involved in the above, which is the expression of a characteristic property of the class of functions to which magnetic force and current belong. They have all the property of continuity which distinguishes the electric current, viz., that of flow in closed paths like an incompressible fluid. It is of the greatest assistance to conceive them as fluxes like the current, not merely as quantities having certain values at certain places. Given one of them, and then forming the others, any one of them may be taken to represent a possible system of either current or magnetic force.

The vector-potential A, for instance, of a straight current C is a flux parallel to the current, its strength proportional to $C \log \frac{a}{r}$, where a is a constant, and r the distance from the axis. Let this flux A be a system of magnetic force, its curl is the corresponding current, which must therefore be B, or the lines of current flow are exactly those of the magnetic force of a straight current.

Similarly, if we find the vector potential of B, say A_0, we know that its curl is proportional to A, so that if A_0 represent magnetic force, the corresponding current is proportional to $C \log \frac{a}{r}$. And so on.

Another way of deducing magnetic force from current will be given in a following article.

Electric Lighting in Theatres.—The Direction of the Imperial Theatres in Russia has contracted with Mr. A J. Rousseau, engineer, for the lighting of the whole of these theatres by electric lights, this system having been adopted as a precaution against fire. His Imperial Majesty the Emperor signed the concession on the 29th ultimo. Swan incandescent lamps will be used, with Bürgin machines to supply the current. There is no foundation for the statement that an American company had secured this concession.

THE ELEMENTARY PRINCIPLES OF ELECTRICITY.

I.

In these papers we propose to give such a brief sketch of the science of electricity, and of the mechanical principles on which it is founded, and in accordance with which all electrical measurements are made, as will enable the general reader to understand the system of units employed in measuring electrical quantities, and the principles upon which the actions of the various appliances employed in electric lighting depend.

At the threshold of physical science we find ourselves face to face with at least three primary conceptions, or quantities which cannot be defined in terms of anything simpler than themselves. They are time, length, and mass.

Each of these quantities, like all others, must be measured by comparison with a unit of its own kind. The unit of time invariably adopted for scientific purposes is the *second of mean solar time*.

The British unit of length is the imperial standard yard. One third of this length, or the foot, is the unit generally employed by engineers. The metric unit of length is the metre, which is subdivided into 10 decimetres, 100 centimetres, and 1,000 millimetres. The centimetre is the unit of length generally adopted by electricians. The metre is equal to 39·370432 English inches, and the centimetre is therefore equal to ·39370432 inch, or nearly ·03281 of a foot. A centimetre may be roughly regarded as about two-fifths of an inch, and a millimetre is about 1-25th of an inch.

The British unit of mass is the imperial standard pound avoirdupois. The standard itself is a mass of platinum, and is defined by the Act which gave it authority as the only standard of *weight*. It is clear, however, that the object of authorising a standard for commercial purposes is to provide a unit in terms of which quantities of material may be measured, and it is an accident that weight is generally taken advantage of for making the comparison. The pound ought, therefore, to be regarded as the unit of mass, not of weight. This is further indicated by the fact that the weight of a pound is different in different latitudes and at different altitudes, while its mass remains invariable, so that if a material standard were adopted as a unit of *weight*, that is, of *force*, it would have to be varied whenever it is moved from place to place, and would only remain the standard so long as it is kept in the same place.

The metric unit of mass is the kilogramme, but the gramme, which is one thousandth of the kilogramme, is the unit generally adopted for scientific purposes. The gramme is approximately equal to the mass of a cubic centimetre of distilled water at the temperature corresponding to its maximum density. It is equal to about 15·43234874 grains, or ·00220462121b. avoirdupois.

Every person is supposed to be provided with the requisite means for measuring time, length, and mass, and when the measurement of any other physical quantity can be reduced to the determination of these three fundamental quantities, it may be regarded as completed, at least theoretically. When any quantity is measured in terms of the fundamental units of time, length, and mass only, it is said to be expressed in *absolute* measure. It will be one of our objects in these papers to show that all electrical quantities may be expressed in terms of the second, the centimetre and the gramme, or in terms of any other set of fundamental units. The system, which is based on the centimetre, gramme, and second is called the C.G.S. system of units.

Geometry is the science which deals with pure space. If we consider space and time together we enter on the subject of kinematics. When we introduce the motion of mass as well as space and time we have dynamics. Thus dynamics must be regarded as the basis of all physical science.

Except when otherwise stated, we shall confine ourselves throughout these papers to the units of the C.G.S. system and the practical units derived from them.

Def. Velocity is the degree of quickness with which anything is moving. The unit of velocity is the velocity of a point which traverses the unit of length in the unit of time. Hence our unit of velocity will be a centimetre per second.

Digitized by Google

The measure of the velocity of any point moving uniformly will then be equal to the number of centimetres passed over by it in the course of a second.

DEF. Acceleration is the rate of increase of velocity. The unit of acceleration is that of a point whose velocity is increased by unity in the unit of time, or, by one centimetre per second in each second, so that the measure of a uniform acceleration is equal to the number of units of velocity added in the unit of time.

DEF. The momentum of a body is the product of its mass and its velocity. The C.G.S. unit of momentum is that of a gramme moving at the rate of a centimetre per second.

When we pass from the consideration of pure kinematics to that of the motion of material bodies, we must have recourse to observation and experiment. Newton summed up the results of such observations and experiments in three brief statements, called the *Laws of Motion*. These, like other physical laws, must be regarded simply as concise statements of the results of experience.

LAW I. *A body under the action of no external force will remain at rest or continue to move uniformly in a straight line.*

Hence we deduce the definition of force, viz.:—

Force is that which changes or tends to change a body's state of rest or motion.

The first law of motion thus furnishes a *qualitative* definition of force. The second law gives its *quantitative* measure.

LAW II.—*Rate of change of momentum is proportional to the impressed force, and takes place in the direction in which that force acts.*

A force is, therefore, proportional to the change of momentum it produces in the unit of time. If we take as unit force that force which produces the unit of momentum in the unit of time, the measure of any force will be equal to the number of units of momentum which it generates in the unit of time. The C.G.S. unit of force is that force which acting on a gramme for a second produces in it a velocity of a centimetre per second, and is called a *dyne*.

DEF. A force is said to do work when it moves its point of application in its own direction, or an agent is said to do work when it overcomes resistance.

The work done is proportional to the product of the force and the distance through which it moves its point of application in its own direction, or proportional to the product of the resistance overcome and the distance through which it is overcome. If the force act vertically, and the body be moved along an incline, in estimating the work done we must measure only the vertical height through which the body is raised or falls, and generally, in whatever direction the force acts, the displacement must be measured in that direction. If the body moves in the *sense* in which the force acts, work is done *by the force*, but if it be made to move in the opposite *sense*, work is done *against the force*. The unit of work is the work done by the unit of force in moving its point of application over the unit of length. The C.-G.-S. unit of work is the work done by a dyne in moving its point of application over a centimetre, and is called an *erg*.

The weight of some particular body, such as the unit of mass, is sometimes taken as the unit of force, and is called a *gravitation* unit. The objection to such a unit is that it varies in different localities, being about one-half per cent. less near the equator than near the poles. If the weight of a pound be taken as the unit of force, the unit of work will be the work done in lifting a pound one foot high against gravity, and this is called a foot-pound. It is equal to about 13,560,000 ergs.

DEF. The power of an agent is the rate at which it can work. The unit of power is that of an agent which can do the unit of work in the unit of time. The C.G.S. unit of power is that of an agent which can do one erg. in one second, and one erg per second is the C.G.S. unit rate of doing work.

DEF. An agent which can perform 33,000 foot-pounds of work in one minute, or 550 foot-pounds in one second, is said to be of *one horse-power*. The horse-power is equal to about 7,458,000,000 C.G.S. units of power. Thus, an agent of one horse-power can do 7,458,000,000 ergs per second, and we can always determine the H.-P. at which any agent is working by dividing the number of ergs done in a second by 7,458,000,000, or, with sufficient accuracy for most purposes, by dividing by 7,460,000,000. The rate of doing work equivalent to 10,000,000 ergs per second is called a *watt*.

Newton's third law of motion is as follows:—

LAW III. *Action and reaction are equal and opposite.*

In the first interpretation Newton gives of this law he points out that whenever one body presses or pulls, attracts or repels, another, it is pressed or pulled, attracted or repelled by the second body with a force exactly equal to that which itself exerts, so that forces always come into existence in pairs, each pair consisting of two equal and opposite forces, or an action and an equal and contrary reaction. Action and reaction together constitute a *stress*, and the forces themselves may be regarded simply as aspects of the stress. It is, however, often convenient to abstract one of the forces, together with the part of the system on which it acts, and to omit the consideration of the other force or opposite aspect of the stress. Thus, we may consider the effect of the sun's attraction on the earth's motion without taking into account the equal and opposite attraction exerted by the earth upon the sun, and the consequent disturbance of that body.

In Newton's second interpretation of the third law of motion, he states the principle of the conservation of energy, so far as it could be stated before the fate of the work done against friction and other similar forces was known.

DEF.—The energy of a system is its capacity for doing work, and is measured by the number of units of work it is capable of performing in passing from its existing state into some standard condition.

A mechanical system may possess energy in virtue of (1) its configuration, or the relative positions of its parts, or (2) of the relative motions of its parts.

The energy possessed by a system in virtue of the relative positions of its parts is called its *potential energy*. The energy which it possesses in virtue of the relative motions of its parts is called its *kinetic energy*.

The work done by a falling weight or a bent spring is due to the potential energy of the earth and weight or of the elastic spring, while the work done by a cannon shot on its target is due to the kinetic energy of the system consisting of the earth and target and the cannon shot moving relatively to them.

The principle of the conservation of energy was stated by Maxwell as follows:—

The total energy of a system is a quantity which can neither be increased nor diminished by any actions between the parts of the system, though it may be transformed into any of the forms of which energy is susceptible.

When work is done against forces which, like gravity, are independent of the motion of the moving body an equivalent amount of *potential energy* is produced.

When work is done against forces which, like friction, are reversed in direction as soon as the direction of motion of the moving body is reversed, an amount of *heat* is generally produced which Joule proved to be always equivalent to the work so done.

When work is done in producing motion in a body an equivalent amount of *kinetic energy* is produced.

Thus, in the most general case, if an agent do work upon a mechanical system, some of the work done has its equivalent in potential energy, some in heat, and some in kinetic energy developed in the system.

Heat is in reality a form of kinetic energy, but it is due to the motions of molecules, and not of tangible bodies.

DEF. The unit of heat is the amount of heat required to raise the unit mass of water from 0°C to 1°C.

Joule showed that the amount of work which, if entirely converted into heat, would raise 1lb. of water from 0°C to 1°C was 1,390 foot-pounds.

Hence the amount of work which, if entirely converted into heat, would raise one gramme of water from 0°C to 1°C is about 42,000,000 ergs. This is called the mechanical equivalent of heat.

NEWSPAPER SCIENCE.

Although we have never been enthusiastic advocates of science for the multitude, we would certainly make an exception in favour of newspapers editors. If, consistent with the discharge of their important duties as promoters of experimental politics, they could spare time to take a few lessons in elementary physics, their clients would be greatly the gainers. We might add that they—the editors—would be spared much ridicule by taking the course we suggest; but ridicule is not a weapon that reaches the anonymous scribe. Life would be unendurable to him—we include ourselves in this observation—if everything he wrote, or permitted others to write, were brought home to him to endorse. Still, in the interests of the public, for whom the journalist professes to live, he might, one would think, include a smattering of science in his professional training. For the writing of certain daily leaders the storehouse of history, both ancient and modern, sacred and profane, seems to have been ransacked from bottom to top, whilst for certain others the learned author has climbed that dizzy height from which, with far extended view, mankind is surveyed from China to Peru—so the admiring reader thinks, and we are not going to undeceive him. But the labour and the study, whatever they may be, are certainly greater than that required, say, for the mastery of Ohm's law, or a right understanding about the conservation of energy.

Ignorance on these two points alone has led the newspapers one and all into a number of extraordinary errors just lately, some of which may not only mislead but seriously injure the public. From the extreme of thoughtless speculation on the capabilities of electricity for any and every purpose under heaven—speculation which led to operations bearing the same name in the Money Market—we are now witnessing an equally thoughtless scare in respect to the danger attending the use of it. This, too, furthers speculation of the material sort, and will, it may be feared, result in the enrichment of a few people who do not believe in alarming letters inserted by newspaper editors, at the expense of a multitude who do.

The leading journal is, as usual, the foremost offender in this respect. It was the first to make known the fabulous merits of a certain kind of battery; it is now the first to get up a scare against the use of it. The other newspapers, not to be behindhand—first, in telling people how they may put money into their pockets, then in telling them how foolish they have been to take the advice—of course follow suit; and then there comes a panic. It is all done in perfect good faith no doubt, the public instructors acting according to their light for the time being in every case. But what we say is, they might spare themselves the necessity of eating their own words, and their readers the expensive luxury of swallowing them, if only they, the learned editors, would take the trouble to understand a little what they are writing about.

The forthcoming pantomimes are the immediate text for alarms. "Some dreadful accident may occur to arouse public indignation," and so forth. Hardly a Christmas passes without some accident, more or less dreadful, generally due, it must be confessed, to the careless use of exposed gas lights. But because some heartless managers contemplate the introduction of electric light in order to add either to the beauties or the horror of the spectacle, we are forthwith warned against its appalling danger. We quite agree that the life of "a super at 20s. a week" ought not to be "put in jeopardy" by any theatrical manager "autocratic" or the reverse. But we do not precisely apprehend where the danger is. Certainly not from a battery sufficient only to charge one small lamp, for that appears to be the thing to be personally feared. The electrical resistance of the human body is very considerable, and in this respect a ballet girl, we imagine, differs in no way from less etherial mortals. We would not so much as singe the hem of her garment to please a thousand theatrical managers; but in sober truth we could not do it if we tried, not at least with the electricity at command in the proposal we are referring to.

Passing from the meretricious brilliancies of the stage, we have been witnessing a grand display of nature's splendours in the heavenly arena far and wide; and this, of course, has brought forth the inevitable crop of startling discoveries. Milwaukee is a place with an outlandish name, and of all the outlandish things which come from America, Milwaukee, of course, is credited with a disproportionate share. It is a modern El Dorado and Golconda of scientific jewels. Such is the virtue pertaining in this wonderful town that during the recent magnetic disturbances, that is to say while the aurora borealis was shining in the firmament above, an

Digitized by Google

electric light was illuminating Milwaukee below, maintained solely by the magnetic disturbance. An eight horse-power engine is usually required to keep that light going. On the night in question Milwaukee appropriated the aurora, and dispensed with the engine. Hence it follows that if the United States of America, which telegraphs this information to Europe for our edification, will only keep us supplied with the requisite amount of "magnetic disturbance," of the 8 h.-p. sample, such as prevails at Milwaukee, our electric lighting can obviously be maintained in a very literal sense "regardless of expense."

These are the natural deductions of people who trust to the newspapers for their guidance in matters relating to electrical science. Of an opposite character were some warnings which originated in the same quarter not long ago in reference to fires. It would be exceedingly dangerous, said the newspaper paragraph, for any fireman to chop an electric lighting wire with his axe, as the current might travel up the handle and do him an injury. The same paragraph even warned him against playing upon any wire charged with an electric lighting current lest it found a passage to earth by way of the jet of water, the hose pipe, and the fireman's body!

STUDENTS' COLUMNS.

These answers are intended to guide, to give information and references, to put the student in the way of getting information, and *not* to give the exact answers that should be written in an examination.

Question 5 (*continued*). Therefore the resistance increases.

$$\cdot 21 \times 28 = 5 \cdot 88 \text{ for an increase of } 28°\text{F.}$$

Thus the resistance of

105·88 feet at 32°F. = resistance of 100ft. at 60°F.

We have seen

250ft. of this wire has R = 1 ohm at 32°F.

and as 105·88ft are, under the above conditions, equivalent to 100ft. under the given conditions,

$$\therefore \frac{100}{105 \cdot 88} \times 250 = \text{No. feet with R} = 1 \text{ ohm at } 60°\text{F.}$$

$$= 236 \text{ nearly.}$$

The percentage increase due to a rise of $t = 15°$F.

$$= \cdot 21 \times 15 = 3 \cdot 15.$$

4. A joint has to be made between the ends of two thick electric light wires. Explain and give sketches of the method of jointing you would employ. In carrying wires, between which there is an electromotive force of 300 volts, through the rooms of a building what method of insulation would you make use of? Show exactly how you would lead the wires to a number of incandescent lamps suspended from a bronze chandelier, and give the reasons for adapting your method.

Ans. For first portion of Answer 5, method of jointing proposed by the Society of Telegraph Engineers in the Rules and Regulations issued by the Society. The Rules were given in Vol. IX., p. 179.

Architects, as a rule, make no provision for pipes or channels for conveying wires, &c., in their plans; but in designing a new building to be lighted by electricity such provision should be insisted on. The arrangements to be followed where no such provision has been made must vary with the circumstances of the case. It should be an axiom with electric light engineers to have an ample margin of safety in their conductors, and to obtain the best protection from damp. The wires should be covered with, besides other insulating material, at least one taping of india rubber. If a small wooden tube could be used in which the wires could be laid, and surrounded with, say, paraffin, the wires being in two divisions of the tube, or in two different tubes, there would be little danger from any short circuit through damp. Or the wires might be insulated with gutta percha, or ozokeritised rubber, but in any case we should prefer to use, in conjunction with such wire, the channels, and further surround the covered wire as described, or with some other cheap resinous insulating material.

The main wires would be carried, as above described, along the joists directly above the chandelier. The chandelier would be, or ought to be, designed with hollow branches, radiating from a larger hollow central stem. Two insulated wires would be taken from the lamp screws, that is, on opposite sides of the branch, through a small hole in the stem, and along the stem to the leading wires, to one of which one wire would be joined, the other wire being joined to the other main wire. The lamp socket would contain contact arrangements, so that the turning of a plug would make or break the circuit of that particular lamp.

[We imagine from the fact that reasons are required, this question was framed to get somewhat into the "individuality" of the examinee. No two answers could be exactly alike, unless the student had been "crammed," because the number of ways of doing these things is practically infinite.]

6. What is the electromotive force in volts of a Daniell and of a Grove cell? What is the electromotive force of the dynamo you are best acquainted with, running at some definite speed, and with some special resistance in circuit? How, exactly, is this electromotive force altered by increasing the speed? In the case of a magneto-electric machine, how does the electromotive force vary with the speed? Explain fully the cause of the difference, if any, in the effect of speed on electromotive force in the dynamo and in the magneto machine.

Ans. Daniell ..... 1·079 volts (Clark and Sabine).
Grove ..... 1·956 „ („ „).
B. Bürgin at 1,550 revs. has E.M.F. of 200 volts } *Electrician*
B_1 „ „ „ „ 160 „ } supple-
C „ „ „ „ 300 „ } ment.
Gramme 1,000 revs. has E.M.F. of 107 volts with ext. resist. = 2·7 ohms ..... } (Adams, Cantor Lectures).
Siemens 1,000 revs. has E.M.F. 42 volts through about 2·2 ohms ..... } „ „

Dr. Hopkinson has shown the following with regard to the E.M.F. of a Siemens machine:—

(1) The E.M.F. is, for a given current, proportional to the speed of revolution of the armature.
(2) The E.M.F. does not increase indefinitely with increasing current, but
(3) Only increases in the direct ratio as the current increases up to about two-thirds of its maximum value.

Mr. R. E. Crompton states that the E.M.F. of the Bürgin machine is directly proportional to speed between 1,000 and 1,700 revolutions.

[We must refer students to Dr. Hopkinson's papers, read before the Institution of Mechanical Engineers in 1879-1880, where they will find references for further information than is given in the papers. The second paper is given in *The Electrician*, Vol. IV., p. 295. It must be remembered that magneto and dynamo machines have the one permanent the other electro magnets. The field of the one is practically constant, and hence E.M.F. is to be taken generally as proportional to the number of revolutions, but in the other case this holds good only within limits. Up to a certain number of revolutions the electro-magnets are constantly increasing in effect, then comes a point after which the field is pretty constant, and the E.M.F. is proportional to the revolutions.]

7. A certain magneto machine, when running at 500 revolutions a minute, produces an electromotive force of 8 volts. What current in amperes will it send through an external resistance of 50 ohms when running at 750 revolutions a minute if its own resistance is $1\frac{1}{2}$ ohm?

Ans. As E.M.F. is proportional to the number of revolutions, the E.M.F. at 750 revolutions is found from

$$500 : 750 :: 8 : x,$$

whence

$$x = \frac{750 \times 8}{500} = 12.$$

From Ohm's law

$$C = \frac{E}{R + r},$$

when

C = current in amperes,
E = electromotive force in volts,
R = external resistance in ohms,
r = internal resistance in ohms.

Putting the values for E, R, and r, we have

$$C = \frac{12}{50 + 1 \cdot 5} = \frac{12}{51 \cdot 5} = \cdot 0233 \text{ nearly.}$$

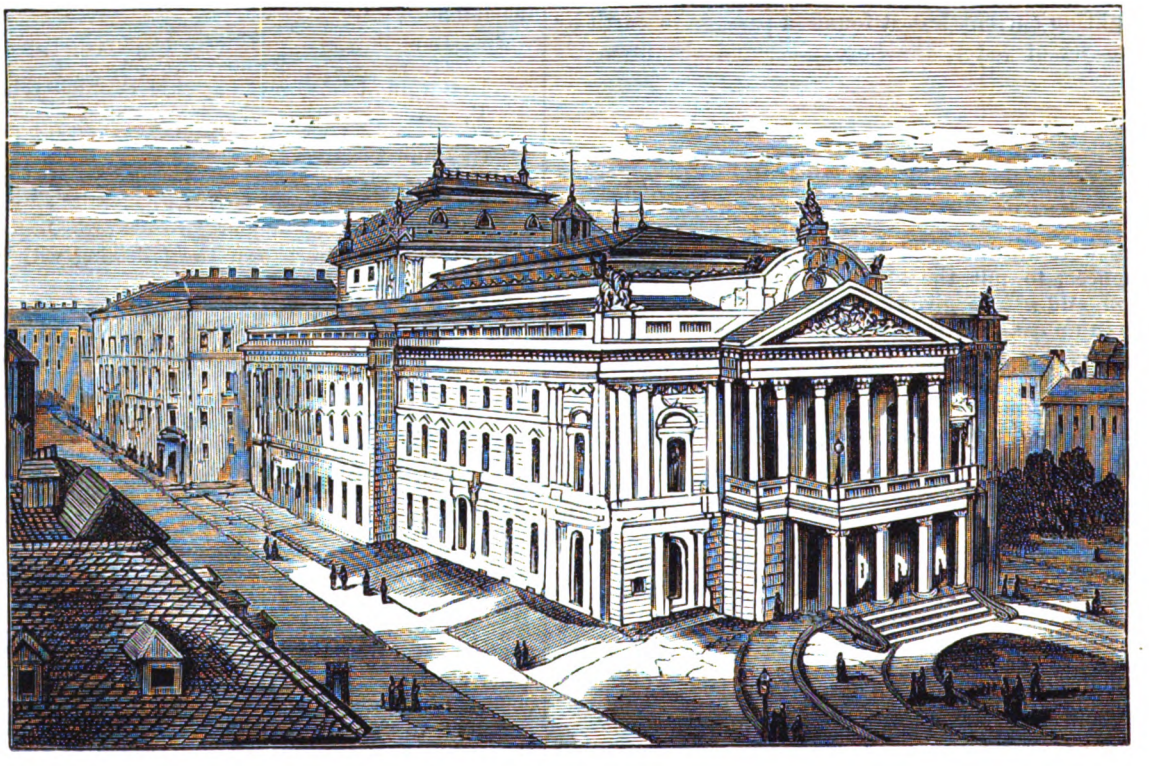
ELECTRIC LIGHTING AT BRÜNN.

BY FRANCIS JEHL.

Brünn, in Moravia, which is the chief manufacturing centre of the Austrian empire, has now beyond doubt the finest installation of electric lighting on this side of the Atlantic. The new theatre, which is owned and governed by the municipal council of that city, is entirely lighted by the Edison system of electric lighting. The building, which occupies a whole square, contains about 1,600 lamps, and has no connection with gas whatever. This theatre has all the modern improvements that can be suggested. Owing to the calamities that have befallen some theatres of late years, the city has taken great precaution to secure a place of amusement which is absolutely safe against fire. The auditorium is separated from the stage by a wall one metre thick, and an iron curtain, worked by hydraulic engines, so that at a moment's notice one part of the building can be separated from the other. All the lights on the stage and auditorium are governed by regulators, and can be varied to any desired intensity. There are six rows of cross lights, each row being divided into three circuits, having 40 lamps each, making in all 720. Each one of these circuits can be regulated, or all together. Then the foot lights, which are divided into two sections, have three circuits each, and contain an aggregate sum of 180 lamps. There are 60 lamps to be used as portable ones, coming from underneath the stage by means of flexible cables. Thirty more lamps, to be worked by flexible cables, come from the first stage gallery, and 60 more for the uprights on each side of the stage, making 1,050 lamps on the stage alone. The main electrolier has 60 lamps, and 110 more are scattered in different parts of the auditorium, amounting to 1,220 lamps, which are operated by regulators similar to those used for gas. The regulators consist simply of resistance coils, made of German silver wire, and are inserted into each circuit which is required to be operated. Each regulator is divided into many parts, so that nicety of variation can be obtained. The resistance and size wire used for each regulator depends upon the number of lamps in its circuit. The regulators used here are so constructed that lamps at 16 candle-power can be gradually turned down until the carbon becomes black. Each row of the cross-lights, as before stated, has three circuits, each circuit containing forty lamps, which are of a different colour, namely, red, white, and green. The object of this is to produce the different colours of the day; for representing the night the green lamps are regulated, and as morning comes on the red lamps come into play, and then the white. We have also an arrangement to imitate lightning. This is done by having an apparatus which will break a circuit, having a strong current, very quickly. The spark thus produced resembles lightning. All main lines, branch circuits, and electroliers are provided with safety cut-outs, which will interrupt any circuit the moment an abnormal amount of current begins to flow. The general plan for regulation may be understood by inspecting Diagram 1. Here R represents the main regulator, which will regulate all lights at the same time. R′ is the regulator that will regulate all the cross-lights at the same time, while R‴ are regulators that govern the circuits in which they are connected. There is a two-pointed switch connected to the first ten top regulators, the object being to throw the red or white lamps in circuit when needed, as the three different colours are never needed at the same time. The diagram shows only one line or pole, the return circuit being common for all. The object of a regulator or resistance-box is to increase or diminish the strength of the current passing through it. It is economical to construct a regulator of a size wire that will just carry the current intended for it, without becoming heated to any extent. The stronger the current the heavier the wire must be, and, consequently, the more the cost. In regulating only a portion of the lights in a system it becomes evident that the electromotive force at the terminals of the machine must remain constant, and that in order to diminish the current in any portion of the system it must be done by inserting a resistance in that circuit. Now, as in the case of lamps in a theatre, the resistance of the regulator depends upon the number of lamps in its circuit; the less the number of lamps the higher the resistance, and the greater the number of lamps the lower the resistance. It is well to use small size wire, joined in multiple-arc, as it gives more surface and therefore does not heat so much as the same weight of metal in one large wire would. To construct a regulator that will regulate with nicety, the following facts must be taken into consideration:—

Let R equal the resistance of the number of lamps used at



Theatre at Brünn.

Digitized by Google

16 candles, while E is the electromotive force required to keep them at that candle-power. By Ohm's law we find that the current is $\frac{E}{R}$, which let us suppose to be C. Having, therefore, found the current that keeps them at 16 candles, it is desired to ascertain the intensity of the current required when they give no visible light. This must be determined by experiment, carefully noting the electromotive force and resistance at that point. Let us suppose that the resistance in this case is R′, and the electromotive force E′, the current therefore being $\frac{E'}{R'}$, which let us suppose to be C′.

The difference in the strength of the current in both cases is found by subtracting C′ from C, which let us suppose to be *a*. Our object, then, is to have a resistance that will produce that difference with a constant electromotive force of E. This can be determined by the following equation, where E equals the electromotive force required to keep the lamps at 16 candles, and C′ the current required to keep them at the

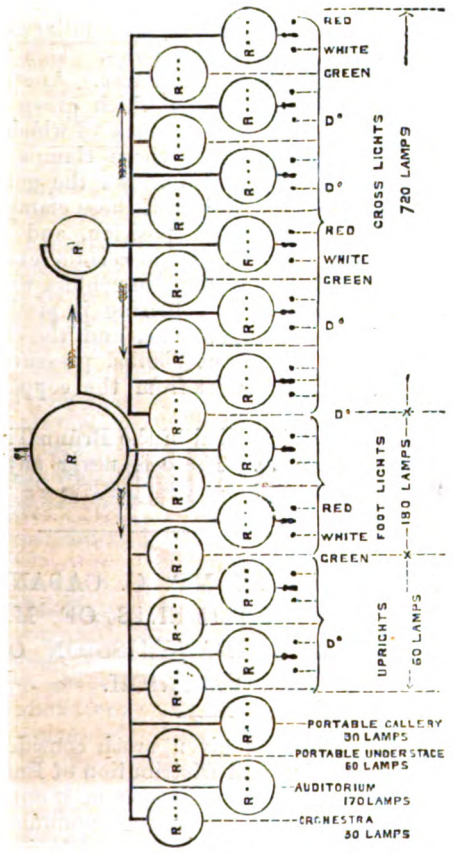


FIG. 1.

invisible points, x being the resistance we wish to determine:—

$$C' = \frac{E}{x},$$
$$C'x = E,$$
$$x = \frac{E}{C'}.$$

Now, as the resistances of our lamps are included in x, the artificial resistance can be expressed by

$$x - R' = \text{artificial res.}$$

Having thus found the resistance required we must find what size wire will carry the current most conveniently. This must be ascertained by experiment. The following formula will answer all practicable purposes:—40 here is a constant already determined by experiment, and I is the intensity of the current—

$$40\sqrt{I} = \text{wire in } \cdot 01 \text{ of mm.}$$

This formula is only good for German silver, which is the best alloy for the construction of resistance boxes, as it does not change its resistance so much with a change in its temperature as other metals do.

Having the diameter of the wire, the length required is easily found by measuring how many meters or fraction of a meter there is to a unit of resistance. Now, when this resistance is inserted into the line, the best effect is produced by introducing it slowly, that is, small portions of it at a

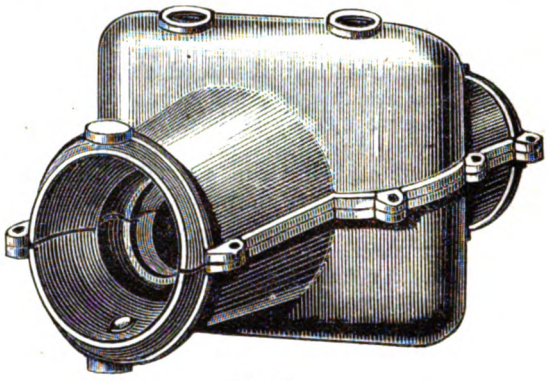

FIG. 2.

time, so as to prevent jumps. This is done by having many contact points on the switch board intended to operate the resistance, the greater the number of points the better the effect produced.

Four dynamo machines known as the K kind supply the current. Each machine is capable of supplying with ease the current required for 250 lamps of 16 candle-power each. The resistance of these machines is ·03 ohms, thus making a

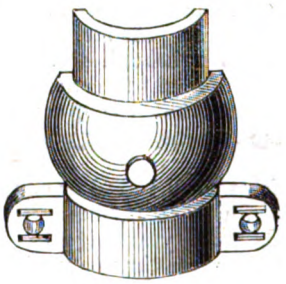

FIG. 3.

ratio of 1 to 20 when the resistance of the lines is taken into consideration. The K machines consist of three magnets, such as are used on ordinary 60-light machines, coupled together. The armature is, therefore, three times as long as the bobbin of the 60-light ones, and consequently has three times the magnetic surface, and at the same time has one-third the dead wire that three 60-light machines have. The weight of wire used on a K is about the same as the weight

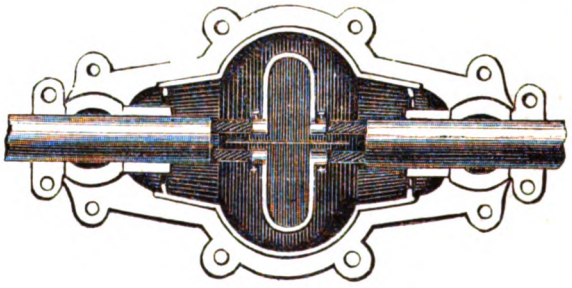

FIG. 4.

used on three small machines. This shows the economy that large machines have over small ones. For example, in the above case the resistance of three 60-light machines coupled together is about ·046 ohm, a certain portion of this being ineffective and yielding no current, but unavoidably so, as it forms a portion of the circuit in which the effective wire lies. This ineffective or dead wire lies at the back and front of an armature, and it is evident that by using the same

Digitized by Google

weight of wire used in three small machines and transforming it into one large machine the loss is much less, as we utilise two-thirds of the wire that would have been dead in the small machines. Then we gain in another point, that is, if we have the same number of coils in the large machine as in the small ones, the speed being the same, we would create an electromotive force of three times that which one small one would. This, however, is not desired; the object is to produce an electromotive force equal to that of the small one. This can be done in two ways, first, by running the machine slower, and, secondly, by making a less number of coils in our machine. (It must be understood that the intensity of the field magnets are supposed to be constant in both cases.) Now, in our case we employ both ways; we run our large machine slower, because it is heavier, and, consequently, would not permit of being run as fast as the small ones, although it would be very desirable. Then we make the large machine of a less number of turns, electromotive force turns, if I may use the term, and fill up the space with current or quantity turns. This makes the machine of a low internal resistance, lower than the coupled resistance of three small ones, and therefore permits of having a heavier load or more lamps than the small ones. This is seen in the above case, where one machine has 250 lamps, and the same amount of wire used in a different manner can only carry 180 lamps. If it were not for mechanical difficulties, that is, if we could lessen the amount of friction generated at the bearings and run the machine faster, we would gain more per weight of metal. This holds true for all machines, large or small. The requirements of a good dynamo machine are, first, that it should transform nearly all the mechanical energy given to it into electrical energy; and secondly, it should be so constructed and used that nearly all the electrical energy can be utilised, and therefore become productive. This can be done by making the resistance of the armature as low as possible, and so constructed that nearly all the wire cuts through the magnetic field. Then, again, the field magets ought to consume as little current as possible. It is found that the greater the weight of iron used with the same current, the stronger the magnetism produced.

All the above facts can be used or employed within certain limits, outside of which it becomes impracticable. It was Mr. Edison's study some years ago to discover where these limits lay, and at the same time to utilise all the laws governing electricity and magnetism in the construction of his machine.

The line that conveys the current from the machine house to the theatre is about 350 meters long, and is laid underground about one meter deep. The electric tubes used are of the latest pattern manufactured by the Edison Tube Company, of New York. These tubes have a much stronger armour than those of previous date, the iron tube encasing the copper mains being nearly double as thick as the first ones. The tubes employed in Brünn are known as the No. 1·5 size, the copper mains containing about 1,296,419 circular mils, which is equal to about 72 No. 10 wire B.W.G. These tubes come in lengths of about 20·5ft., the copper projecting about two inches, which allows of being connected together by means of copper clamps formed into a V shape so as to allow for expansion and contraction. The two wires are held firmly apart inside the tube by cardboard washers, which prevents them from touching each other, or the iron pipe that protects them. This is then filled with some insulating composition, manufactured by the tube works, especially for their tubes. The tubes are all then tested, by means of a Thomson high resistance reflecting galvanometer, with 200 Daniell elements. No tube is allowed to pass unless it gives a resistance of over 300 megohms. The following is briefly the manner in which tubes are laid. Each length, when required, is taken, and the copper terminals thoroughly cleaned, so that they admit of being well soldered to the expansion clamps. It is then laid into the ground, care being taken to prevent any dirt coming in contact with the ends. Another such a length is then placed at about two inches distant, a junction box being placed at that point, and the V shaped clamps connected to the ends of the tubes. After these have been thoroughly fastened together, by means of screws, they are soldered so as to insure perfect contact everywhere. In order to do this perfectly a jet of hydrogen gas is used, as the heat so generated is greater than that which can be obtained in any other practicable way. It must be remembered that it takes a large amount of heat to solder such joints, as the copper is large, and being a good conductor, the heat dissipates very fast. After this is done the box is cleaned out, and a piece of cardboard well saturated with paraffin is inserted between the two poles. The cover is then bolted on, and filled with insulating compound, the two holes on the top being then plugged up by means of screw plugs.

The electric tubes permit of being bent to nearly an angle of 90 deg., and tests have shown that it does not impair their insulating qualities in the least. Fig. 2 shows the latest form of junction boxes, which have many advantages over the old ones. One of the improvements consists in being a little higher than the old ones, and when full of compound, which when cold shrinks, still protects the cardboard that separates the poles. It has happened in the old ones that, after the shrinkage of the compound, the vacuum produced would suck in moisture, and by capillary action would communicate some between the poles. This objection is entirely surmounted in these new boxes. Another improvement consists in the iron clamps which grasp the tubes at both ends of the junction box, an idea of which can be got from Fig. 3. The application of these clamps is best seen by inspecting Fig. 4, which also shows the general way of connecting up tubes. The object of these clamps is to hold firmly the tubes in a horizontal position, and at the same time allow them to deviate to a certain extent without causing the copper clamps to come in contact with the box.

The hydrogen gas used in soldering is produced by the action of sulphuric acid upon zinc, and the charges are so proportioned as to give about 250lbs. pressure per square inch. The gas is used direct from the copper cylinder in which it is generated.

Of the 1,600 lamps installed in the Brünn Theatre, about 1,000 will burn at a time. There is never any occasion to use them all at once.

THEORY APPLIED BY MR. G. CABANELLAS TO THE RECENT EXPERIMENTS OF M. MARCEL DEPREZ ON THE TRANSMISSION OF POWER FROM MIESBACH TO MUNICH.

M. Cabanellas, who has given much consideration to the questions of Production and Distribution of Energy by Electricity, and who is the author of a system of automatic working of such a problem, has just communicated to the "Academie des Sciences" of Paris the following theory:—"*In the transmission of mechanical energy by means of two identical dynamo-electric machines, the ratio of the speeds does not express the value of the return; the return is equal to the product of the ratio of the speeds into the ratio of the fields.*"

Those who have had experience with dynamo-electric machines have remarked that for a given number of revolutions, per unit of time, of the generating machine, the maximum work is not obtained from the receiving machine when this is allowed to go at half the speed of the generating machine; but for a large number of types of machines the receiving machine should go at two-thirds the speed of the generator to obtain the maximum mechanical work. This fact, however, is in contradiction to a theory which is found in several scientific works, a theory which admits implicitly or explicitly the equality of the fields of the generator and receiver. But it must be granted by every one that from Lenz's law there follows the necessary reaction between the field and the moving current in each machine. The theory of M. Cabanellas takes exact account of all experimental results; his example shows how great this reaction may become with high speeds. M. Cabanellas's communication

Digitized by Google

is, moreover, of great interest on account of the general method of reforming the electric elements which he applies to the particular case of the experiments of M. Marcel Deprez as to speeds, differences of potential and current observed at Munich by the engineer who carried out the following experiments in accordance with the instructions of M. Marcel Deprez.* Now that very exact instruments for measuring current and difference of potential are obtainable, the value observed by the easy method of M. Cabanellas for the total work given electrically to the generator has every reason for being much more exact than the value of the work obtained by interposing a transmission dynamometer between the mechanical source of power and the generating dynamo, since at a speed of 2,200 revolutions per minute the error introduced in the traction pull and thence in the work of one revolution is multiplied thirty-six times in the determination of work per second. In this method M. Cabanellas has profited greatly by his former experiment on the increase of internal resistance of machines when running.

"In a series of studies on electrical machines communicated to the 'Academie des Sciences,' I have analysed the theoretical reasons which differentiate the reflex magnetic and electric elements of a machine according as this machine is worked mechanically to create electric currents or is worked electrically to produce mechanical work. But No. 15 *du Tome XCV. des Comptes Rendus* (October 9th, 1882) has on page 633 a note from M. Marcel Deprez, the conclusions of which prove to me that in the interest of science and its applications it is indispensable to call attention to the results of the experiments of which I have spoken in a manner sufficiently concise for the figures to be followed. M. Marcel Deprez gives the results of an interesting experiment on the transmission of power to a great distance, which he has made from Miesbach to Munich (57 kilometres of overhead telegraph line). According to the note the receiving Gramme machine developed half a horse-power measured on a brake at 1,500 revolutions per minute, an identical Gramme generator at Miesbach running at 2,200 revolutions. M. Marcel Deprez concludes that 'subtracting the passive resistances of every kind the ratio of the work reproduced at Munich to the work expended at Miesbach was as $\frac{1500}{2200}$ = more than 60 per cent.' It was a departure from the above-quoted theory that caused M. Marcel Deprez, in the preceding assertion, to make an error which is very far from negligible, since I will show that *from the results of this experiment, the return, instead of being about* 60 *per cent. was about* 20 *per cent.*, that is to say, about one-third as much as the author of this experiment imagined. The above-mentioned notes, besides the speeds of the machines and the work reproduced, give only the resistances (*in repose*) of each of the two machines (470 ohms) and the total resistance (line wire and return) of the telegraphic circuit (950 ohms). There would not be in this the elements necessary for a numerical estimation, but I find the following series of figures in a recent publication which relates to the experiment at Munich (*Bulletin de la Cie Internationale des Telephones*):—Power transmitted, $\frac{1}{2}$ h.-p.; resistance of each machine, 460 ohms; resistance of line, 1,000 ohms; speed of generator, 2,100 revolutions; speed of receiver, 1,400 revolutions; difference of potential between the terminals of the generator 2,400 volts, and between the terminals of the receiver 1,600 volts; current, 0·5 ampere. It will be seen that the two sources of information present in what they have in common an agreement sufficient to permit both to be taken as the base of an approximate calculation. It is reasonable to take without selection the figures of the most complete source which can be applied, although they are a little different from those of the experiment noted by M. Deprez. Let i = current, E the electromotive force of the generator, e that of the receiver, r the resistance of the generator *when working*, ρ that of the receiver, R that of the line, E the difference of potential at the terminals of the generator, $E_{,}$ the difference of potential at the terminals of the receiver, t the mechanical work reproduced per second (kilogramme-metre), t' the useless work of the receiver through rubbing of the brushes and resistance of the air, g the acceleration of gravity. Neglecting at first the work done uselessly we have:—

$$E_{,} i = g t + i^2 \rho \therefore \rho = \frac{E_{,} i - g t}{i^2} = \frac{1600 \times 0{\cdot}5 - 10 \times 37{\cdot}5}{0{\cdot}5^2} = 17000 \text{ ohms},$$

and $e = E_{,} - i \rho = 1600 - 0{\cdot}5 \times 1700 = \frac{g t}{i} = 750$ volts.

But the resistance of the machine in repose is 460 ohms, and therefore the increase for 1400 revolutions is $1700 - 460 = 1240$ ohms. The increase for 2100 turns will be $\frac{1240 \times 2100}{1400}$, and hence for the generator $r = 460 + 1860 = 2320$ ohms, and $E = E + r i = 2400 + 2320 \times 0{\cdot}5 = 3560$ volts, and therefore the return is $\frac{e i}{E i}$ or $\frac{e}{E} = \frac{750}{3560} = 21{\cdot}06$ per cent., admitting that the current is not less at the receiver than at the generator, which would again lower the return. As verification, $i = \frac{E - e}{r + R + \rho} = \frac{3560 - 750}{2320 + 1000 + 1700} = 0{\cdot}55$ ampere, which would represent a loss of $\frac{5}{100}$ ampere $= \frac{1}{11}$ of the current in a total length of wire of more than 100 kilometres. The positive and negative tensions vary gradually from a difference of 1200 to 800 volts with the potential of the earth. If it is wished to take account of the work t' reproduced uselessly in the receiver, the formula becomes $E' i = g t + g t' + i^2 \rho_{t'}$, $\rho_{t'} = \frac{E_{,} i - g (t + t')}{i^2}$ $e_{t'} = E_{,} - i \rho_{t'} - \frac{g t'}{i}$, and since $\rho_{t'} = \rho_0 - \frac{g t'}{i^2} \therefore e_{t'} = E_{,} - i \rho_0 = e_0$, which should be *à priori*. The useless work t' is easy to measure dynamically, and even electrically, by a method which I have communicated, and which has been inserted in the *Comptes Rendus*. In the absence of direct measurements, we may estimate this useless consumption at $\frac{1}{10}$ of the mechanical power reproduced by the receiver, *i.e.*, at 3·75 kilogramme-metres per second. The above formula gives us for $t = 37{\cdot}5$, and $t' = 3{\cdot}75$, $\rho = 1550$ ohms, $e = 750$ volts without any change, increase for 1400 turns = 1080,

$$r = 470 + \frac{1080 \times 2100}{1400} = 2090 \text{ ohms},$$

$E = 2400 + 2090 \times 0{\cdot}5 = 3445$ volts, $\frac{e}{E} = \frac{750}{3445} = 21{\cdot}77$ per cent. Using the figures of M. Deprez's note for inert resistances it would be $i = \frac{3445 - 750}{1550 + 950 + 2090} = 0{\cdot}58$ ampere. All our conclusions stand. If in the numerator of i we take account of the difference of potential lost through derivation, on the line we find 0·51 ampere. We have judged it interesting to pass through all the details of the reconstruction of the electric elements, for we might have at once applied the formula.

$$\text{Return} = \frac{g t}{E i + \frac{N}{n}\left[E_{,} i - g\left(t + t_{,}\right)\right] - a i^2 \frac{N - n}{n}}$$

which applies if the line is perfectly insulated. $N_{,}$ $n_{,}$ are the speeds of the generator and receiver, a is the resistance of the machine in repose at the strength of current i. But the formula

$$\text{Return} = \frac{g t}{E\,I + \frac{N}{M}\left[E_{,\,I} I - g\left(t^{\,I} + t_{,\,I}\right)\right] - a\,I^2 \frac{N - M}{M}}$$

in which $E_{,I}$ is the difference of potential between the terminals of the machine worked at a speed M by a current I,

* M. Cabanellas has since acquired proof of the authenticity of these figures.

Digitized by Google

the work got out by the brake being t_1 and the useless work t', a_1 being the resistance at rest under the strength of current I. The value of the current I at the generator being greater than i, the value of the current at the receiver approximately, in this case where the line is imperfectly insulated the formula

$$\text{Return} = \frac{g\,t}{E\,I + I^2\left[\frac{N}{n}\left(\frac{E_1}{i} - g\left(\frac{t+t'}{i^2}\right) - a\,\frac{N-n}{n}\right.\right.}$$

may be employed. With the preceding approximate figures a calculation would give I = 0·65, which would reduce the return to less than 15 per cent.

"The kind of calculation which I have just made shows how useful and practical is the consideration of the increase of internal resistance of machines when working, also with what ease it allows a great error to be rectified, and of finding the return which a measure of the power expended at Miesbach will give, a measurement which is particularly easy and exact if, as has been remarked, the generator is driven by a separate gas engine. In fact, when M. Deprez admits that the return is equal to the ratio of the speeds, he implicitly admits the equality of the magnetic fields of the generator and receiver, whereas through the reflex actions of which I have spoken (electric current in movement inducing magnetism) the generating field was more intense than the magnetic field which the same current would develop with the armature in repose or turning with an open circuit, and the field of the receiver was less intense than this field not influenced, so that according to the figures given the field of the receiver in this experiment would be three times less intense than the magnetic field of the generator.

"(Signed) "G. CABANELLAS."

ON THE ACTION OF THE MICROPHONE.*

BY PROFESSOR JAMES BLYTH, M.A.

In the microphone transmitter, as usually employed in circuit with a battery and a Bell telephone, we have essentially two pieces of carbon resting lightly against each other, through which the current passes. That the instrument may work effectively two things are requisite—first, that the carbons be always in contact, or, at least sufficiently near for the current to pass between them; and, secondly, that they be not pressed together so tightly as to prevent any motion of the one relatively to the other. This state of things is sufficiently well described by the term "loose contact," first used, I believe, by Professor Stokes.

To understand the action of the microphone, we have to find out what effects are taking place at the loose contact when the instrument is acted upon by sonorous waves. These are twofold—first, the effect produced by the sound waves (that is, the variation of density due to the condensations and rarefactions of the air) which pass directly through the air when they arrive at the loose contact; and, secondly, the effect produced by tremors set up in the entire instrument, wooden supports and carbons together, by the sound waves which strike against it, and are thereby stopped.

For distinction, we may call the first of these the *air effect*, and the second the *tremor effect*.

In my experiments I have endeavoured to arrange the instrument so as to isolate these effects, and, as far as possible, examine each of them separately.

To isolate the air-effect, it is obviously necessary, either to fix the carbons rigidly in their supports, so as to avoid any motion of the one relatively to the other, or to use a strong current, and place them just clear of contact with each other.

The following experiment illustrates how this may be done:—

A, B, and C (Fig. 1) are three blocks of brass firmly fixed to a heavy wooden sole-plate, S. To the top of A is soldered a piece of brass rod, *a*, about 2in. long and $\frac{5}{8}$in. bore. To the top of B is soldered a piece of similar tube, *b*, about 4in. long. Through C passes a fine screw worked by a milled head, *c*. A piece of carbon rod, *e*, is fixed firmly into *a*, and has a hole $\frac{1}{4}$in. wide drilled through its centre. A long piece of carbon, *f*, pointed at one end, passes tightly through the tube *b*, and can be moved backwards and forwards by the screw *c*. A piece of india rubber tube is passed over the left end of the tube *a*, and carries the mouth-piece M. By means of two wires which are soldered to the carbon rods, they are put in circuit with the battery (20 Grove cells) and the telephone T, which must either have a smaller resistance or be placed in a separate circuit from that containing the battery, so as to be acted upon inductively. When the carbon *f* is screwed tightly into the hole *e*, the circuit is completely closed, and no sound uttered into M is heard at T. But when *f* is drawn gradually back, until small electric arcs are seen to pass between *f* and *e*, every sound uttered into M is distinctly reproduced in the telephone T.

Here we have clearly only the air-effect acting, and that solely upon the small electric arcs passing between the carbons. I have found it, as yet, somewhat difficult to get the sounds to last for any length of time, in consequence of the arc distance soon getting too great for the current to pass and requiring re-adjustment. When the arc begins and ends a sharp click is heard in the telephone; but in the interval during which the arc lasts the sounds heard in the telephone are distinct.

As far as the tremor effect alone is concerned, it is obvious that the microphone action must depend, either (1) upon the variation of resistance due to variation of pressure, or (2) to variation in the extent of surface contact due to the elastic yielding of the carbons under pressure.

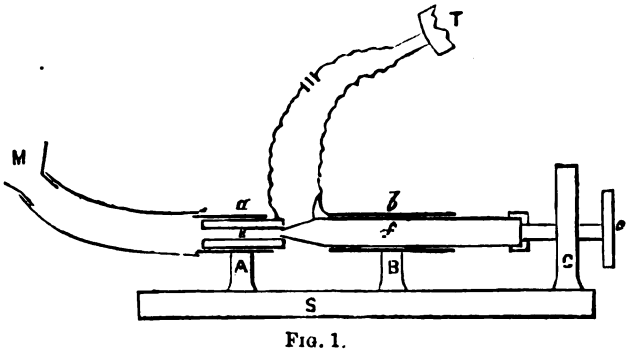

FIG. 1.

To test the first of these cases, I made, about two years ago, some experiments on the effect of pressure upon the specific resistance of carbon. For this purpose, I took a short length of carbon rod, and soldered wires to it at a short distance from each end. By means of these wires, the resistance of the carbon rod was balanced in the Wheatstone bridge. Pressure was then applied by means of a lever to the carbon in a longitudinal direction. No appreciable variation in the resistance was observed, even under considerable pressure, and it only became manifest when the pressure was sufficient to bend or crush the carbon.

I have recently repeated these experiments with the greatest care, and found the same results. I observe, also, that similar experiments, with the same result, have quite lately been made by Professor Sylvanus Thompson. Hence we can hardly, I think, believe that variation of specific resistance due to pressure can have the slightest effect in producing the microphone action. To test the second cause above mentioned, that is, the variation of resistance due to variation, in the extent of surface contact due to elastic yielding under pressure, I experimented as follows:—

In the apparatus already described I replaced the tubular carbon by a finely pointed piece, so as to have two fine carbon points exactly opposite each other. The resistance of the points was balanced in the bridge in the usual way. Pressure was then applied by a known number of turns, or parts of a turn, of the fine screw, and the change of resistance noted. The screw was then brought back to its former position and the pressure relieved, so as to allow the elasticity of the carbon to act, and restore the points to their first condition. It is obvious that, if the change of resistance were due merely

* From *Proceedings of the Royal Society*, Edinburgh.

Digitized by Google

to elastic yielding, it should now be the same as before. This I found not to be the case. From the gritty nature of the carbon, the points of contact I found were perpetually changing, and hence the variation of resistance produced in this way obeyed no regular law.

From this irregularity it is impossible, I think, to conclude that this cause could explain the transmission of musical sounds, far less articulate speech.

As far as my experiments go, the following appears to be something like the true explanation of the microphone action: —What I have termed the air and the tremor effects take place simultaneously. The tremor effect produces a jolting of the carbons, sufficient to allow momentary minute elastic arcs to take place between the points, which are just clear of contact with each other. Simultaneously with this the air effect comes in, and on account of the variations of density due to the condensation and rarefaction of the air, acts upon the minute electric arcs so as to vary their resistance. The tremor effect explains merely the production of the musical pitch of the sounds heard in the telephone, whereas it is to the air effect that we must look for the transmission of the quality of the sounds uttered into the microphone transmitter.

The microphone is thus so far a delicate make and break analogous to the old Reis transmitter, with the important addition, however, of momentary gaps filled with a material which is sensitive to the harmonic variations of the atmosperic density which constitute sonorous vibrations.

CORRESPONDENCE.

LAMPS FOR CARRIAGES.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In answer to your correspondent, "W. W.," we beg to say that the electric lighting of a two-horse carriage is quite feasible. We have not merely electrically lighted a tricycle, but we have taken a box containing three accumulators, each weighing 14lb., in a hansom cab, in railway carriages and elsewhere, and with it we have kept three incandescent lamps burning. But for the present difficulty of obtaining incandescent lamps which will work with a small electromotive force we might have fed six lamps with the same box instead of the three, which were all we could purchase. The lamps in question are two-candle Swan lamps, each of which will work up to four candles with only a small electromotive force. Within a short time we expect to be able to work a reading lamp with an accumulator weighing only a few pounds.

We may mention also, for the benefit of those who like to read in bed, that we have found the above-mentioned portable accumulator box and one of the incandescent lamps very convenient, as all risk of fire, the bugbear of the burner of the midnight oil, is avoided by their use.—Yours, &c.,

AYRTON AND PERRY.

The Faure Electric Accumulator Company, 71, Queen-street, Queen Victoria-street, E.C., Nov. 22, 1882.

ELECTRIC TRICYCLES.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In reply to your correspondent "Chancery Lane," I have great pleasure in informing him that the motor used by me in my "Legal" Electrical Tricycle is a new arrangement of the "Piot Motor." The apparatus, including a specially constructed battery, is very simple and light, it can be attached to an ordinary tricycle, and will not cost more, I should think, than £10 to £12.—Yours, &c,

JNO. MACDONALD, C.E.

5, Southampton-buildings, Holborn, London, Nov. 21, 1882.

LITERATURE.

THE BATTERY AND THE BOILER.*

The publishing season is now in full swing, and if the east wind, bringing snow and ice in its wake, did not tell us that Christmas was at hand, the books which are issued for amusement and instruction would inform us. Mr. R. M. Ballantyne is well known as a successful writer of tales for the young. His books are always readable, and in many of them, if not in all, he manages to combine a good deal of instruction with lighter reading. One feature in his works is deserving of the highest praise—it is that there is nothing in them which the parent may not safely allow his children to read, without fear of exciting the imagination with deeds of horror, or weakening the moral principle. Mr. Ballantyne takes advantage of the great interest now felt in electrical subjects to construct a story which dwells considerably upon electrical matters. The hero is born at sea, during a terrible thunderstorm. He grows up inquisitive, and especially so in all that concerns electricity, and luckily has a cousin who is able to direct his inquiries. By and bye he is found plodding away in an office, doing his duty manfully, but taking every opportunity to increase his knowledge. His employer recommends him as secretary to one of the electricians on board the "Great Eastern" during her Atlantic cable laying expeditions. The author has the opportunity of describing the operation of cable manufacture at the Construction and Maintenance Company's works at Greenwich, the operations of laying and picking up the cable he relates most graphically, the difficulties encountered and surmounted, the hopes and fears of those on board, and the ultimate success of their work. The hero, after the completion of his work in the Atlantic, goes eastward on a cable expedition, is wrecked, is saved with three friends by means of a raft, thrown on to an island which proves to be the rendezvous of a horde of pirates. What adventures he meets with here, how he escapes and joins the "Great Eastern" at Bombay, taking part in the cable laying between India and England, *viâ* Aden, &c., must be gathered from the book. Suffice it to say that the story, though in some parts a little far-fetched, carries the reader with it to the end, where it will be found that the characters marry and are given in marriage, and, we suppose, live happily afterwards.

We trust that this book may be selected by many a parent and friend for a Christmas present, inasmuch as it will undoubtedly tend to interest the reader in the application of electricity. Pleasure and profit will go hand in hand, for, with one or two slight exaggerations, the statements made in the book will not have to be contradicted by future reading; they are accurate, and have evidently been carefully selected.

DISPLAY OF AURORA.

On Friday and Saturday last, Nov. 17 and 18, a very severe magnetic storm was experienced in our islands, all over Europe, and also in America. We give the following extracts from various newspapers describing the storm and its effects.

The *Scotsman* of Nov. 18, says:—"The weather in Edinburgh yesterday was calm and fine, with light haze in the lower atmosphere and a serene sky, diversified with patches of cloud. Just after sundown, there commenced a splendid display of aurora borealis, a concomitant, no doubt, of a great magnetic storm which yesterday produced such extensive derangement of telegraphic communication, and which certain observers would seem to associate with a remarkable development of sun-spots now in progress. At first, the aurora presented a purplish glare, brightest in the west, but shooting out in broad bands right across the heavens. The appearance of the western sky was, indeed, at one time, such as to give many the impression that a

* *The Battery and the Boiler; or, Adventures in the Laying of Submarine Electric Cables.* By R. M. BALLANTYNE. (Illustrated.) [James Nisbet and Co., 21, Berners-street, London.]

Digitized by Google

serious fire must have broken out in the outskirts of the city. As the evening wore on, the phenomenon continued with a varying brilliancy, which would have been even more striking but for the seven-days-old moon that shone in the south-west. A vast expanse of diffused radiance showed from behind a dark cloud-bank that covered a considerable portion of the northern heavens, while ever and anon broad pulsing rays of pale greenish light shot upwards as far as the zenith. The display, as a rule, was most vivid in the north-west, but at times the whole northern half of the sky was brightly illuminated. After nightfall sharp frost set in. Our Kirkwall correspondent, telegraphing at 7:45 last night, says :—To-night, shortly after darkness set in, there was a very unusual display of aurora borealis here. The sky all round turned very red, shortly afterwards pink, and then yellow. The shooters, instead of going up towards the zenith, ran along the sky from east to west, and the different colours diffused were very pretty. Shortly afterwards the sky to the south became very hazy. The barometer is falling briskly—29·32; wind south-west. The aurora to-night was in the south, and attracted the attention of all. The weather is extremely cold; the frost this morning was severe. Yesterday's magnetic storm appears to have been the most remarkable experienced for many years, and it led to a serious delay in the telegraphic service. The earth currents on the Post Office telegraph lines first appeared about 10 a.m. yesterday, almost simultaneously on the east and west and north and south circuits. This is very unusual, for it is but seldom that such currents affect lines running east and west, but it will be observed that the rays of the aurora last night were projected in this direction. These currents varied very rapidly both in strength and direction all day, with the exception of two hours, from 1 to 3 p.m., when they were absent. After that time they again increased in intensity until 11:30 p.m., when they slightly abated in strength, though they continued as variable as ever in direction, and, singularly enough, they appeared to affect the east and west lines to a greater extent than those running north and south. Where the number of wires and other circumstances admitted, 'looping' (*i.e.*, metallic circuits, without earths) was successful, although, as is well known, more power was required to obtain the same telegraphic speed. It may be mentioned that on Thursday there was a brief appearance of magnetic disturbance, but it lasted only for an hour or two. Where the wires could not be looped yesterday, the ordinary circuits were entirely stopped when the earth currents attained a certain force, and for a time they reached a maximum of about 60 volts."

The aurora was also seen in great beauty, both in London and the provinces. Letters from Dover, Sidmouth, Cirencester, and news from all points of the compass, testify to the vividness of the display. It may be noted here that a very large group of spots was on the sun on Wednesday, and on Thursday it was not far from the centre. This group was composed of six spots, and was easily distinguishable by the naked eye. It is the largest group that has been seen for many years.

Mr. E. J. Creese, of Cirencester, who examined the aurora with a spectroscope, gives the following account of his observations :—"The usual yellow-green line was constant, showing strongly, and with the slit of the spectroscope opened a little wider a bright line appeared in the red when the instrument was directed to the more luminous streamers. I also several times saw a fainter line in the indigo. About ten minutes past six two or three faint bands of light appeared in the green and blue parts of the spectrum. The bright yellow-green line showed plainly whenever the spectroscope was directed to the north and east, but in no other part of the sky."

On the Wednesday preceding this auroral display, a very heavy fall of snow was reported as having taken place over a wide area of the British Islands, accompanied by a severe gale, particularly in the south.

The following accounts were received from the United States : —The *Daily News* New York correspondent, telegraphing on Sunday, says :—"A remarkable electric storm, extending the entire width of the continent from Boston to San Francisco, prevailed during Friday night. At Omaha the aurora borealis was so brilliant that night was made as light as day. At Cheyenne, Denver, and at points in California and Washington territory there were similar displays. At St. Paul, Minnesota, the sky was of a blood-red colour, making an effect at once grand and fearful. Telegraph communication was seriously interrupted, and various experiments were tried to work the wires, without success, until it was discovered that by taking two wires from the ground between two given points, and joining their ends a circuit was formed that could be worked. In this way eight wires were made to do the service of four. Electricians agree that the disturbance was unlike any heretofore experienced, as it appeared to act upon the wires in strong waves, constantly changing polarity of current." The *Standard* correspondent says:— "An electric storm, the widest and severest ever known, has swept from New York West to Omaha and Kansas City, and northwards as far as the telegraph goes. Messages were almost entirely stopped. The successive negative and positive waves of the current passed from east to west, alternately intensifying and neutralising the battery current, and the instruments were repeatedly fused. At Nashville the galvanometer varied 80degs. Bangor worked a message a distance of 700 miles without a battery. At Milwaukee, by means of the storm alone, an electric light requiring eight horse-power was kept burning for some time. The auroras were very remarkable." *The Times* correspondent adds the information that "cold weather, with snow, accompanied the storm in many places."

From the Continent we learn, through the *Daily News*, that "M. Flammarion, the well-known astronomer of Paris, received a telegram this morning (Thursday, Nov. 17) from M. Bruguière, at Marseilles, informing him that there is at the present moment a quadruple spot on the sun's surface, visible to the naked eye, and of far greater size than the earth. Magnificent aurora boreales are again reported from Norway. Strange to say, this is the seventh time this year that the northern lights have made their appearance simultaneously with the presence of enormous spots on the sun's surface." The *Standard's* Berlin correspondent says, telegraphing on Friday night :—"Winter commenced here last night in earnest. This morning all the streets of the capital were found covered with snow, which up till evening showed no symptoms of melting again. This is full early for winter in Berlin. One of the worst inconveniences of the storm is the interruption of most of our chief lines of communication, both railway and telegraphic, with places at a distance. We have since mid-day been cut off from London, Paris, St. Petersburg, and Cologne. This, however, is, I find, attributed by meteorologists chiefly to a violent electric disturbance, which has prevailed simultaneously with the snowfall." The *Daily Telegraph* of November 18 says that their special wire to Paris was interrupted. A message from their Vienna correspondent on Thursday night says :—"In consequence of an occurrence of northern lights, telegraphic communication with and from Vienna has been interrupted to-day. It has been a dull, rainy day, and my thermometer stands at three and a-half Réaumur, whereas the last observation of northern lights in Vienna was in the middle of summer."

PARISH OF ST. PANCRAS.

Like many other authorities, the St. Pancras Vestry has recently been investigating the position of the electric light, and the Lighting Committee has just received a report on the subject from their clerk, Mr. T. E. Gibb. This gentleman points out that the consideration of the subject has been forced upon the authorities by recent legislation, and, among other things, remarks that :—

The electric light has now, it is considered, passed the experimental stage as regards its efficiency, and although undoubtedly improvements will be made from time to time, the only serious subject of consideration is the cost. The duties of an authority under a license or provisional order, after taking steps to protect itself, will be simply to supply electricity, and such authorities will not have to concern themselves as to the merits or demerits of any particular lamp or burner, or even as to the purposes to which the electricity may be applied. The electricity will be supplied by meter. The safety of the householder will have to be secured by some means. Dr. Hopkinson, in his evidence before Mr. Chamberlain's committee, said that with a fusible point any undue quantity of electricity will be prevented from passing the point, and that with it "you can make the thing absolutely safe." The plan is to introduce a short length of lead into the main conductor entering the house; this lead has a carrying capacity sufficient for the largest current which the lights in that house can require, so that if by any mischance the amount of electricity supplied should be in excess of the requirement, so as to produce risk of accident from the heating of the conductor, the piece of lead would be fused and fall, thus interrupting the circuit, and cutting off the supply. The introduction of fusible points for the purpose of securing safety in the event of the electromotive power or pressure being excessive need not in practice be limited to the point of the introduction of electricity into a house. Mr. Edison has introduced these points as frequently as desired, and they can be fixed to each light, if thought safer, by means of safety plugs, which interrupt the copper conductors with a piece of lead wire, and if the current be broken by fusion, and a light or series of lights, as the case may be, put out, the current can be connected again by simply inserting a new plug. Electric light, whether considered as to efficiency as a means of artificial light or as to cost, must be a matter of interest to the vestry even so far as it is a question of general public interest; but it is especially important to the vestry as a local authority, because its extensive use involves an interference with the control of the public streets. At the same time it interferes with the vested interest of established companies heretofore entrusted with the supply of gas, or with municipal authorities who have themselves undertaken to supply gas in their districts. It has been laid down as an axiom in connection with the introduction of the electric light that, although there are gas monopolies the rights and duties of which must not be ignored, there is no monopoly of artificial light. I have before referred to the fact that the local and other authorities who may be entrusted with the supply of electricity are not to concern themselves as

Digitized by Google

to the manner of its application except so far as may be necessary for the protection of the general interests of such authorities.

Electricity is dealt with by the Act of Parliament not as for lighting purposes only, but as a "source of power and light." The Act contemplates that by means of accumulators electricity may be used for many purposes. Such accumulators have been used already for storing electricity for lighting large rooms, for lighting the passenger steamers from Newhaven to Dieppe, and the Pullman express from London to Brighton. The extent of the use of accumulators is yet but little known, and it is said that by their use the electric energy can not only be stored for purposes of lighting, but for motive power (such as the working of tramway cars and omnibuses), the propulsion of electric cars (as a substitute for cabs), tricycles, &c., the driving of lathes, printing presses, sewing machines, and other small machines, elevators, and pumps, &c. This possible extension of the uses of electricity makes the subject more important to a local authority than even the great question of public and private lighting. . . . . It may be observed here that if a municipal authority be entitled to receive at the hands of Parliament a protection because it has fulfilled its duty, then a private company may also be entitled to similar protection in a district such as St. Pancras. The reasons for such protection being claimed on behalf of the local authorities who have the supply of gas in their own hands are such, however, as should lead the vestry to be extremely careful in guarding the public interests in the streets.

The Electric Lighting Act seems to assume:—1. That great progress has been made in the subject of electric lighting. 2. That this progress warrants Parliament affording facilities for the introduction of the system. 3. That it is more desirable in the public interest that the authorities entrusted with the care and control of the public streets should be responsible for the supply of electricity than that such responsibility should be entrusted to private companies. 4. That where for any reason the local authority is not disposed to take the responsibility of supplying electricity, those who require it should still have the power to obtain it on the most advantageous terms, and that therefore facilities should be given for private companies to afford such supply where a reasonable demand may be made for the same. 5. That where power to supply electricity is given to a private company, the local authority should be empowered subsequently to take over the responsibility from the Company.

It must be admitted that electricity can never be supplied economically unless supplied over a large area. Several witnesses examined before Mr. Chamberlain's committee concurred in the opinion that a fair experience as to the economy of the electric light could only be made in a limited district covered by a population of say 50,000. The vestry will at once admit that under such circumstances the supply of electricity should be placed under some such parliamentary control as is now provided. It is quite clear that "over head" wires for private supply are a source of danger and inconvenience, even only to the limited extent that they are at present in use, and therefore any extensive use of electricity must involve a disturbance of the public streets.

By Rule 2 of the Board of Trade, made under the Electric Lighting Act, it is provided that, when applications for provisional orders authorising the supply of electricity within the district of any local authority are received by the Board of Trade from such local authority, and also from any other authority, company, or person, the Board of Trade will give a preference to the application of the local authority of the district in every case where, in the opinion of the Board of Trade, no special circumstances exist which render such a preference inexpedient. This rule does not provide for a preference to the local authority in case of application for a license. The omission may be accidental, but it leads to the question as to the difference of the value of a license as compared with a provisional order. The rules of the Board of Trade require much the same formalities for a license as for a provisional order, and objections may be made to each. The chief difference seems to be that as a provisional order requires confirmation by Parliament, it is open to be opposed in the same manner as a parliamentary Bill, and the cost of such an opposition in all probability would exceed the cost of an opposition before the Board of Trade. One reply to this is that the probabilities of opposition are remote, seeing that it has already been decided that preference is to be given to the local authorities. Of course, if a local authority took up the question merely with a view of keeping private companies out of the district, and without any *bonâ fide* intention of dealing with the subject, a parliamentary opposition, or an opposition before the Board of Trade would no doubt be effective, but if the vestry take up the question with a *bonâ fide* intention of doing what is best to be done under the circumstances, I think a provisional order could be obtained without fear of opposition and at a very small cost. Moreover, I think the vestry would be in a better position, having a provisional order rather than a license to contract under the provisions of the Act with "any company or person for the execution and maintenance of any works necessary for the supply of electricity." It will be observed that the license shall be for a period not exceeding seven years, and can only be renewed if given to a company subject to the consent of the local authority, while there is no limit of time for which a provisional order may be granted. It is provided by Section 27 of the Act that where any private company is authorised by a provisional order or special Act to supply electricity within any area, any local authority may, within six months after the expiration of 21 years, or a shorter period if such be specified, require such company to sell their undertaking upon terms of paying the then value of all lands, buildings, works, materials, and plant of such company suitable to, and used by them, for the purposes of their undertaking. To be in case of difference determined by arbitration.

The following applications for consent to the granting of a license under Section 3 have been received:—The Jablochkoff Electric Light and Power Company, Metropolitan (Brush) Electric Light and Power Company.

The following notice of application for provisional orders under Section 4 have been received:—Metropolitan (Brush) Electric Light and Power Company, the Gülcher Electric Light and Power Company, the Edison Electric Light and Power Company, the West Middlesex Electric Lighting Company, the "Pilsen," "Joel," and General Electric Light Company; the "Ferranti, Thompson, and Ince" Company; the Swan United Electric Light Company.

Upon these applications and notices, the first question that arises is whether the vestry will apply for a license or a provisional order to supply electricity in St. Pancras. If the vestry are so disposed they can afterwards arrange for carrying out the scheme with one or more of the electric companies. It is necessary, however, before obtaining either a license or a provisional order that definite general arrangements should be made, inasmuch as the Board of Trade require before considering any application that full particulars shall be given. If the vestry decide to apply for a provisional order they should be well advised as to the details of such order by some practical electrician, the object of such advice being so that the vestry may secure in their order all powers which may now or hereafter prove valuable, and at the same time guard themselves from unnecessary obligations. This is the more necessary as very much has been said for and against the many points associated with this subject by persons whose judgment and experience does not warrant them in offering advice. I believe there are several persons of eminence as electricians who are prepared to afford assistance to local authorities, amongst them Dr. Siemens, Sir William Thomson, Professor Jenkin, of Edinburgh; Dr. Hopkinson, and Messrs. Clark and Muirhead.

The general obligations which would be imposed upon the vestry in a provisional order are contained in Sections 11 and 19 of the Act, which are as follow:—Section 11: Any local authority who have obtained license, order, or special Act for the supply of electricity, may contract with any company or person for the execution and maintenance of any works needed for the purposes of such supply, or for the supply of electricity within any area mentioned in such license, order, or special Act, or in any part of such area; but no local authority, company, or person shall by any contract or assignment transfer to any other company or person, or divest themselves of any legal powers given to them, or any legal liabilities imposed upon them by this Act, or by any license, order, or special Act without the consent of the Board of Trade. Section 19: Where a supply of electricity is provided in any part of an area for private purposes, then, except in so far as is otherwise provided by the terms of the license, order, or special Act authorising such supply, every company or person within that part of the area shall, on application, be entitled to a supply on the same terms on which any other company or person in such part of the area is entitled under similar circumstances to a similar supply. These general obligations may be considerably modified or altered by the provisional order, and while there is no doubt that such an order would contain conditions in which a supply could be demanded by any person within the area of supply, it is nevertheless believed that these conditions will be guarded by provisions similar to those contained in the Gas Works Clauses Act, so that a local authority would not be compelled to supply at a loss.

Mr. Farrer, the Permanent Secretary to the Board of Trade, in his evidence upon the reasons which led the Board of Trade to prepare and introduce the Electric Lighting Bill, speaking with reference to the obligations to be imposed on the authorities who may undertake to supply electricity, intimated, with reference to the provision of Section 19, "except in so far as is otherwise provided by the license, order, or special Act authorising such supply," that these words would depend for their meaning entirely upon the terms of the order or license, "because the thing is so new that it would not be desirable to tie the authorities too tightly." No doubt, therefore, although there will be a disposition to impose such conditions upon the local authority as will secure a *bonâ fide* attempt to carry out the provisions of the Act, at the same time there will be such protection as the circumstances necessarily demand, so that the obligations imposed, at least, in the early provisional orders, will not, probably, be so onerous as some persons contemplate. If the vestry obtain a provisional order, it will be quite competent for them to contract with one or more companies to supply electricity, and in such a case the vestry's obligations would not, probably, exceed those which they have as a sanitary authority or road authority, where the vestry take care to insert in their contracts clauses providing for indemnification by the contractors against any damage, by way of compensation or otherwise, which the vestry may become liable to pay, as the authority primarily responsible.

There is one advantage, I think, specially in favour of the vestry of St. Pancras taking up the new powers for the purpose of lighting. It is that, if the vestry were to commence operations in an area, say a mile square, and taking a spot near the junction of Tottenham Court-road and Euston-road as the centre, they would be able to light the three great railway stations and hotels of the London and North Western, the Midland, and Great Northern Railway Companies, the Metropolitan Railway, University College and Hospital, the Vestry Hall, as well as many large establishments such as Shoolbred's and Maple's. Such an area of a mile square would be a fair one to test a complete installation, as regards economy. The cost of such an installation might be, according to the evidence given before the committee of last session, about £200,000 for 50,000 lamps, or about £4 per lamp. There would probably be no difficulty in securing a contract with a good company who would embark the necessary capital with such customers as those named. If there is any probability of the vestry applying for a provisional order, notice thereof must be given without delay, although the giving of the notice will in no way commit the vestry to proceed further. If the vestry decide not to apply for powers either by provisional order or license, then I think the committee should be authorised at once to put themselves in communication with the companies from whom notices have been received in order that the vestry may secure in any license or order to be obtained all necessary provisions for the purpose of giving the vestry full control over the streets (and, if possible, power to contract with the lighting companies to execute for such companies any works which may involve the disturbance of the streets), as well as power to secure the adoption of suitable central sations; for the supply of electricity to the public lamps; for limiting the period of concession; and for purchasing the rights of the company afterwards if the vestry should see fit so to do.

In conclusion, it may be observed that there is nothing in the Electric Lighting Act to prevent electric lighting companies or private persons from supplying any place they choose without any parliamentary powers whatever, provided they can do so without breaking up the streets. The Act does not take away any powers which existed in this respect before it was passed, but simply refuses in the interests of local authorities, to furnish companies with a new privilege of breaking up streets without the assent and concurrence of the local authority, or, at all events, without the local authority having had full opportunities of objecting to the application for such powers, and of putting forward their own *primâ facie* preferential claim. Upon this it might be remarked that the vestry have already

Digitized by Google

granted permission to private persons to disturb public streets, for the purpose of laying down electric wires. It is a question whether such an act on the part of the vestry was not *ultra vires*, and it is very probable, now that parliamentary action has been taken, that objection would be made to the vestry granting such a permission in the future otherwise than in accordance with the provisions of the Electric Lighting Act.

(Signed) THOS. ECCLESTON GIBB.

BIRMINGHAM AND WARWICKSHIRE BRUSH ELECTRIC LIGHT AND POWER COMPANY.

A special general meeting of this Company was held at the City Terminus Hotel on the 22nd inst., under the presidency of Mr. G. M. Felton.

The CHAIRMAN stated that the meeting had been convened consequent on the action of certain shareholders. The directors considered that this action was inimical to the interests of the Company, and that if persevered in it would probably ultimately be ruinous to them. At their last meeting he gave them a *resumé* of the Company's business. They were then in negotiation with several large towns, and they had a contract at that time which he then informed them was about to be signed. That contract, which was for an installation of 40 lights, had been signed, and the lights were either now running or would be in a day or two. They were also at the same time in negotiation with several works to put up the electric light for manufacturing purposes. A circular then appeared from Mr. Whiteley, and about the same time Sir Charles Bright's letter was published, showing that the British Electric Light Company had, concurrently with the Anglo-American Brush Company, the right to use the Lane-Fox incandescent lamp. This statement came on the Board as a surprise, and they were blamed for not having taken proper precautions in looking through the agreements before the prospectus was issued. When the prospectus was issued, it was lodged with the Company's solicitors. They looked it through. The Hammond Company looked it through, and passed it: and the Anglo-American Brush Company looked it through, and it was returned to the Company. Thus this Company *bonâ fide* purchased the exclusive rights to the Lane-Fox lamp. The directors still hold that opinion, and they asked the shareholders to support them in it. At that time Messrs. Ingledew and Ince were the Company's solicitors, and feeling that it would be more satisfactory to the shareholders, inasmuch as those gentlemen were also solicitors to the vendors, the directors placed the matter in the hands of Messrs. Linklater. On the very day that Mr. Whiteley's first circular was sent round the directors had a circular printed, and the envelopes addressed, for calling the shareholders together, and asking their opinion as to the course to be taken with regard to Sir C. Bright's letter. They submitted that circular to Messrs. Linklater. They were then in negotiation as to the repurchase of the Lane-Fox license, and they did not issue the circular, thinking that in a few days they would bring the negotiations to an end, and be able to place before the shareholders something tangible which would put the Company in a much better position. He would remind them that by the Electric Lighting Bill the consumer could use any lamp he pleased. Mr. Whiteley's circular contained many statements which were the reverse of complimentary, and he had issued similar circulars to other companies in which he held a few shares. He had stated that there were numerous actions lodged against this Company. The writ, however, which Mr. Whiteley referred to was lodged by himself, and a gentleman, named Sprangue, had petitioned. There was no other action at that time but that of Mr. Whiteley. It was not the case that any shareholder in this Company had had a penny of his subscription returned to him. Immediately he heard of the action taken by Mr. Whiteley he ordered the business they had in view to be set on one side, stating with respect to the Company's money at the bank that not a penny of it should be spent on plant till this matter was settled. Much had been said respecting the retirement from the Board of Mr. Evans and Captain Inman. The latter gentleman, however, attended their meetings only twice, and as he came up from Liverpool for the purpose he was evidently put to considerable inconvenience. He gave reason for resigning. Mr. Evans did give a reason. The directors were at that time negotiating for the repurchase of the Lane-Fox license. They differed about the amount, and Mr. Evans could not go with them. Consequently he resigned, and nothing could have been more straightforward than the conduct of that gentleman. He himself had felt at the time that he should like to resign, but he had seen on reflection that he should not be doing his duty to his friends if he had taken that course. The Company had now every prospect of doing a fair business. Negotiations had again been opened that day with the vendors, and they had an offer by which very nearly one-third of the capital would be returned to them. Their capital was now about £75,000 or £76,000; and if they had to pay a dividend, that could be done better with a capital of £50,000 than with a capital of £75,000. He asked the shareholders to support the directors in these negotiations, and they would come to no terms unless they were agreed to by the shareholders. As to winding up the Company, he did not know the reason for such a suggestion. He asked them to support the directors in the shareholders' interests. When the negotiations to which he had referred were completed, a circular would be sent to them; and he thought they would then have a very fair prospect of a good business in front of them.

Mr. RATCLIFF moved, "That it is the opinion of this meeting that the recent litigation which has been commenced is most prejudicial to the true interests of the company, and every opposition should be offered to all the hostile proceedings against the company."

Mr. THOMAS BEARD seconded the motion.

Mr. HAMMOND, in supporting the resolution, stated that he did not wish to introduce one discordant note into the proceedings, but he could not allow to go unchallenged the statement that the Hammond Company passed and approved the prospectus of this company. It was true that the prospectus of this company was submitted through the Hammond Company to the solicitors of the Brush Company, but he maintained that the Hammond Company where in no way liable in the matter. The Hammond Company passed on their license word for word as they received it from the Brush Company.

Mr. D. EVANS supported the resolution, and in doing so explained the circumstances of his resignation. He had been of opinion at the time that a full claim should be made upon the Hammond Company for the mistake referred to; but his co-directors were then in favour of a compromise. Nine days after his resignation, however, he found that the directors were pursuing the very same mode of attack on the Hammond Company which he had recommended.

Mr. INCE disclaimed any liability on the part of his firm for having approved the prospectus of the company. The prospectus was prepared by the promoters, and his firm had nothing to do with it. He held, too, that no one had taken shares in the Company on the strength of the statement complained of—that the Company had exclusive rights as to the Lane-Fox license.

The resolution was put and carried.

The Hon. R. MOLYNEUX then moved, and Dr. MACKENZIE seconded, the following resolution, which was carried:—"That the chairman having reported to the meeting that negotiations were pending with the various parties interested, with a view to an amicable arrangement of the difficulties with reference to the Lane-Fox light, be it further resolved that, in the opinion of this meeting, it is desirable that an amicable arrangement of the nature suggested should be come to, with a view to the carrying on of the business of the Company, and that the terms of any arrangement should be submitted to the shareholders for their approval before the same is finally concluded.

A vote of thanks to the chairman terminated the proceedings.

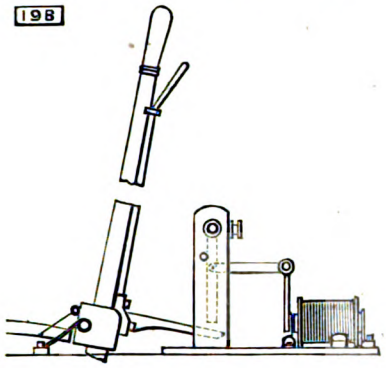
RECENT INVENTIONS.

ABSTRACTS OF SPECIFICATIONS.

198. IMPROVEMENTS IN ELECTRIC BLOCK SIGNALS AND ELECTRIC LOCKING APPARATUS FOR LEVERS WORKING SEMAPHORES AND POINTS ON RAILWAYS, &c., *J. Radcliffe, Retford, Notts.*—*13th January*, 1882. 6*d*.

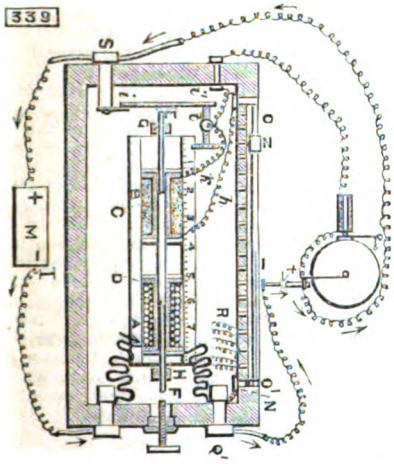
The object of the invention is to prevent the signalman from lowering his signal until he has



received "line clear." The signal lever is locked by means of a vertical bar suspended from its upper end over a projecting tongue, attached to and forming part of the clip lock of the lever. A link attached to the armature of an electro-magnet is connected with the bar as shown in the figure. The electro-magnet is connected with the block signalling instrument at the station in advance, and in such a manner that a current is only passed to the magnet when the instrument is at "line clear." When the current passes, the electro-magnet attracts its armature, draws the bar free from the projecting tongue of the lever clip lock, and the signalman is able to move the lever. In addition to the above the inventor claims a block-signalling apparatus.

339. IMPROVEMENTS IN REGULATING ELECTRIC LAMPS, &c., *E. de Pass, London.*—*23rd January*, 1882.—(*A communication from B. Abdank, commonly called Abakanowicz, Paris.*) 6*d*.

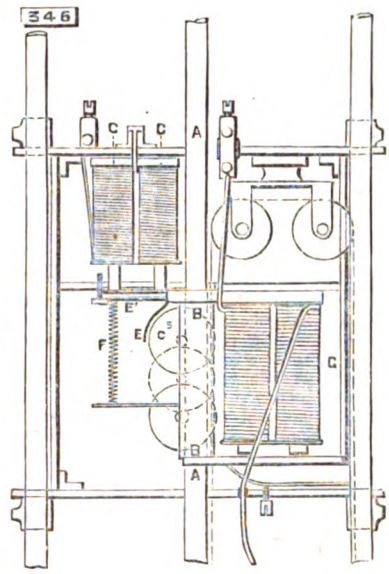
The principle of the invention is the introduction of a resistance balance, as the inventor calls



it, into the circuit of the lamp, which measures the resistance of the arc. The figure illustrates, in section, one form of this balance. A and B are two movable solenoids, one in the main circuit, the other in a shunt. Through these passes a core C D, having non-magnetic extensions C E and D F, which slide freely in bearings G H. The main current passes from terminal I of the machine M by Q, coil A, and Q^1 to the lower carbon of lamp. The derived current is taken from Q^1 through terminal N; it then traverses resistances R—only a portion of which are shown—in the box, enters a movable indicator Z—travelling over a graduated scale—and passes through rod O O^1, traverses *h h*, enters shunt solenoid B, and out through wire *k* into *t*, rod *i i* held by a weak spring, and terminal S. By this means a resistance interposed in the circuit can be measured. Suppose that on the introduction of such resistances C D approaches solenoid B; if then, by means of Z, additional resistances P R be inserted in the circuit of B, the attraction of A will become greater than B, and C D be attracted that way, so that by adjusting Z an equilibrium will be produced, and the resistance required to produce it be ascertained. Moreover, A and B are movable on a slide, and their position with regard to C D changes their attractive force upon this core. This reciprocal motion, indicated on the graduated scale of the slide, in combination with a short travel of C D, also allows the resistance introduced into the main circuit to be measured.

346. IMPROVEMENTS IN ELECTRIC LAMPS, &c., *R. E. B. Crompton, London.*—*24th January*, 1882. 8*d*.

This relates to improvements in arc lamps. The action of the lamp will be understood by reference to the figure, and the following explanation. When no current is passing the gearing frame B B rests within the main frame in its lowest position, the rack rod A A being free to descend through it until stopped by its carbon resting on the lower carbon. When the current enters the lamp it passes through the helix of the main magnet G, lifts the frame B B, and with it the rod A A through its proper stroke, thus parting the carbons and establishing the arc. When thus lifted the frame B B brings the soft iron end E^1 of the brake E within the attractive influence of the fine wire feed magnets C C. So long as the



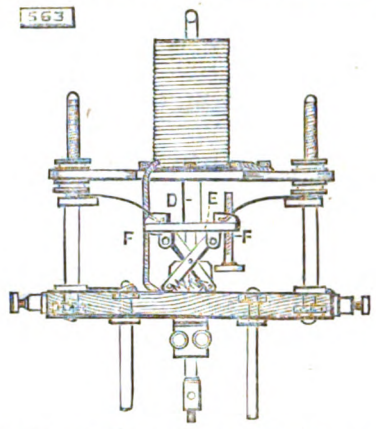
difference of potential at the two sides of the arc remains normal, the current through C C is only sufficient to give it attractive power to balance the opposing regulating spring F which presses the brake E on brake wheel C^3. When the difference of potential exceeds that for which the regulating spring is regulated, the feed magnets overcome the spring, lift the brake off the brake-wheel, and allow the rack rod A A to descend until the difference of potential is again normal. An improvement consists in the provision of a long fine wire of high resistance, in connection with, say, the positive terminal of the lamp and earth, the object being to provide a leakage wire for the static charge which is acquired by the lamp. Another improvement consists in an arrangement for cutting the lamps out of circuit.

378. SIGNALLING APPARATUS FOR RAILWAYS, *W. P. Thompson, Liverpool.*—*25th January*, 1882.—(*A communication from W. W. Gary, Boston, U.S.*)—(*Not proceeded with.*) 4*d*.

The object is to provide a simple, reliable, and inexpensive signal mechanism for use at crossings, curves, stations, and other places at which audible or audible and visible signals are required to be given; and it embraces the use of a magneto generator or dynamo machine driven by passing trains so as to develop an electric current which is utilised to actuate the signals.

563. IMPROVEMENTS IN ELECTRIC LAMPS, *A. J. Jarman, London.*—*6th February*, 1882. 6*d*.

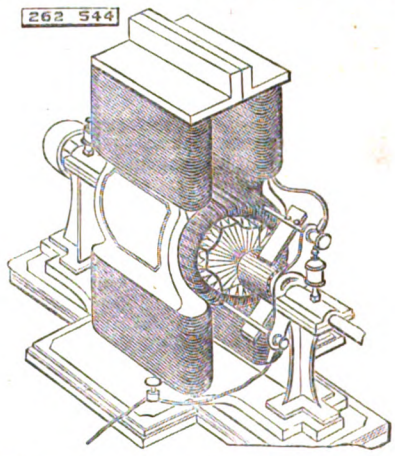
The construction of the lamp will be understood from the figure. The base of the core D is provided with lugs carrying pins, F F, against which slide cross bars, pinned at their centres. When a current flows through the electro-magnet the core is drawn upwards, the cross arms are



straightened and force the gripping pieces against the upper carbon rod, thus lifting it and establishing the arc. The slightest decrease in the magnetisation of the core causes the cross arms to touch the bed-plate, extending them, releasing the carbon road, and so shortening the arc.

262,544. DYNAMO-ELECTRIC MACHINE, *James A. Jenney, Fort Wayne, Ind., Assignor to the Fort Wayne Electric Light Company, same place.*—*Filed April* 15, 1882.

Claim.—(1). The combination, in a dynamo-electric machine, of four electro field magnets, which, with their connecting plates and field segments, are made in two solid continuous masses of iron, so formed and joined in a plane passing either vertically or horizontally through the centre of the armature axis that the field magnets in such casting shall be in line with each other and in the two castings parallel with each other, and which are wound with their field coils in such directions that the two magnets in each casting shall have their similar poles joined in the field segment connecting them, and that the two field segments shall be of opposite magnetic polarity with respect to each other, said two castings to constitute, when joined and bolted together, the entire iron framework of the machine, exclusive of the armature and its mounting, with a cylindrical soft iron armature, smooth and uniform in thickness in surface, mounted and revolving between the field segments aforesaid upon an open skeleton or framework of wood and brass or other non-magnetic material, adjustable in all directions from its central axis, the whole constructed, combined, and operating substantially as described and set forth. (2). In a dynamo-electric machine,



a skeleton or framework for the mounting and carrying of a cylindrical iron armature, consisting of two hubs, made of brass or other non-magnetic material, with radiating arms of like material, adjustable in length by being set as screws into their hubs, and supporting at their extremities wooden bars pressing against the inner surface of the armature, substantially as described and set forth.

232. An Improved Permanent Way for Electric and Telephonic Conductors, *H. R. Meyer, Liverpool.*—17*th January*, 1882. 6*d*.

The inventor constructs an insulated underground permanent way for wires, by means of blocks or slabs of glass, or glazed or unglazed earthenware rendered moisture proof by dipping in hot asphalte or other suitable substance. The slabs are grooved for the reception of the wires, and laid one over another in layers, each slab being dovetailed into its predecessor and follower.

297. Improvements in Galvanic Batteries, &c., *J. and A. J. Higgin, Manchester.*—20*th January*, 1882. 6*d*.

This invention includes the substitution of tin for the zinc elements in batteries, and a simple means whereby the tin is recovered in a form suitable for certain chemical manufactures. Inside a stoneware jar a hollow cylinder of tin is placed. Inside this cylinder is placed a porous cell. In the outer cell dilute sulphuric acid is placed, and in the porous cell a carbon rod surrounded by pyrolusite or native peroxide of manganese broken small. When in action the sulphuric acid produces proto-sulphates of tin and manganese, which remain in solution. The tin is subsequently separated by adding to the saturated solution sufficient peroxide of manganese in fine powder to cause the protosulphate of tin to become persulphate. The liquid is then diluted largely with water, when a precipitation of stannic acid or oxide takes place. This is subsequently washed, thrown on a filter, drained to a paste, and is then ready for further treatment for chemical purposes.

300. Improvements in Fire-extinguishing and Alarm Apparatus for Use in Theatres, &c., *W. R. Lake, London.*—20*th January*, 1882.—(*A communication from H. S. Maxim, Brooklyn, New York.*) 8*d*.

The invention consists of a circuit-closing device, formed of two metal plates, each forming a spring, and separated from each other by a piece of fusible material insulated from the plates. One of the plates carries a point, and the whole is fixed in the wall or other part of the building. When the temperature reaches a certain height, owing to fire, the strip of fusible material melts, and the plates approach each other and close the circuit, in which is included the following apparatus:—A hammer, the head of which strikes on mechanism for actuating an alarum, the hammer being let loose by the attraction of the armature of an electro-magnet in the circuit. The arm of the hammer at the same time operates a series of levers, which liberate a weight, which in turn acts on a lever which opens a valve, and allows water to flow into a pipe running round the buildings, from whence it can be directed to the seat of the fire. To localise the emission of water, however, at the point where the fire has broken out, the inventor places nozzles at intervals along this pipe, fitted with quick matches, which communicate with a charge of gun-cotton. The explosion of this blows off the cap of the nozzle, and permits the flow of the water. These nozzles are fitted at convenient intervals over the building. By a modification of this arrangement the inventor includes in the circuit an apparatus for producing carbonic acid gas.

305. Impovements in Electric Lamps, *J. N. Aronson, London.*—21*st January*, 1882. 6*d*.

This relates to the construction of the globes of incandescent lamps with reflectors formed of the same material as the globe itself, the reflective surface being produced by silvering, enamelling, or other means.

359. Improvements in and Connected with Electric Lamps, *J. N. Aronson, London.*—24*th January*, 1882. 8*d*.

This relates to incandescent lamps, and has for its object the combining of several carbons, either in one globe or several clusters of carbons in glass tubes in one large globe, so that on the failure of one, another can be substituted for it, and put in circuit either automatically or by hand. One arrangement, when several carbons are used, is to enclose each terminal or connecting wire in a glass tube fused around it, and then to arrange the tubes in a group and fuse them into a mass, which may be fixed in the globe by fusion or like a stopper. The ends of the wires are formed into contact pieces. The socket is provided with contact pieces in connection with the leading wires; these may be either sliding or stationary, and the inventor brings these into contact with the terminals of one of the carbons at a time, either by hand or by an automatic arrangement in connection with an electro-magnet and armature, so that on the failure of a carbon a fresh one may take its place.

361. Improvements in and Relating to Electrical Conductors or Cables, *W. R. Lake, London.*—24*th January*, 1882 ——(*A communication from H. A. Clark, Boston, Mass., U.S.*) 6*d*.

To prevent inductive action the inventor places a body of conductive material of considerable size, relatively to the size of the conductors in the cable, close to the insulating coating of a series of conductors, so that the electric impulses expend their energy on the conducting material. No two conductors, also, are allowed to remain next one another for the entire distance they traverse. The second part of the invention refers to a method for keeping the wires in a cable at their relatively proper distances from each other during the process of vulcanisation.

377. Improvements in Electric Lamps, *Sir C. T. Bright, Bolton Gardens, London.*—25*th January*, 1882. 6*d*.

The figure illustrates one form of the inventor's lamp. The action is as follows:—When the current passes through the two circuits, A A—thick wire electro-magnets in main circuit—draw up sliding frame C C by attracting armature B, at the same time G—and the opposite similar armature not seen in the drawing—being attracted by poles I of fine wire magnets in shunt circuit—grasps hold of carbon holder J J by jaws at F, and rises with it. K is an armature fixed to contract lever L—shown in side view in Fig. 2. K is attracted by the other poles M M of the fine wire magnet, and thereby brings L into contact with N whenever the arc gets too long. L and K are connected to the fine wire magnet, which, being cut out of circuit, cease to attract G, and the carbon holder is free to all. L is, however, at once brought back by spring O to its place of rest, the jaws again grasp J J, and the proceeding is repeated till the arc is adjusted to its normal condition.

386. Improvements in the Construction of Cores for Cables, &c., *W. T. Henley, Plaistow.*—26*th January*, 1882. 6*d*.

This relates to the construction of a core with multiple conductors, which may be used for a number of circuits or a few, a switch connecting all the conductors in one or in separate circuits, from two upwards, according to the direction in which it is turned. The conductors of the core are first insulated separately and then all enclosed in another coat of insulation, being next served with yarn and protected with wires in the usual way. The improvement consists in surrounding the core with strong manilla or Russian hemp laid up into closely spun yarns, which are laid round the core in long spirals and then served with galvanised steel wires of small size; the cable is then covered with tape or yarn and compound as usual.

436. Improvements in Electric Telegraph Printing Apparatus, *J. Imray, London.*—28*th January*, 1882.—(*A communication from J. M. E. Baudot, Paris.*)—1*s*.

This relates to an electric telegraph printing apparatus with multiple transmissions. In this system the sending of a letter includes two operations—First, the transmission by the signal; Second, translation of this signal and impression of the letter. The signals are formed by means of commutator levers, worked either by an operator or automatically by the machine itself. The letters are represented either by the action of a single commutator or by that of several combined. At the receiving station the signals are reproduced by means of movable mechanisms actuated by electrical currents, and corresponding respectively with the commutators of the sending station. The number of transmitting levers and of the corresponding movable receiving instruments depends upon the number of distinct combinations which it is possible to effect with them, and also upon the number of letters to be transmitted. The movements of the movable receiving instruments are communicated at the receiving station to a translating instrument which stores them and effects their translation. During the time employed in translation the line is utilised for transmitting other signals.

441. Improvements in Electric Railways, *C. F. Varley, Bexley Heath, Kent, and W. Judd, Penang, Straits Settlements.*—28*th January*, 1882. 4*d*.

This invention consists of a metal conductor laid in a groove cut in a sleeper, which is rendered non-conducting by being desiccated by superheated steam or hot air, and subsequently impregnated with insulating material, such as paraffin, &c. The sleepers are covered with guard plates fastened on them, which do not entirely close the upper surface of the sleeper, but are so arranged as to leave a space sufficient to allow a roller or rollers connected with the car to make contact with the conductor, so as to convey the electricity from the conductor to the electric motor in the car. The electricity is supplied to the conductor by dynamos at suitable places. Methods for insuring good insulation of the conductor are also described.

489. Improvements in Electrical Batteries, &c.—*G. Skrivanhoff, Paris.*—31*st January*, 1882.

This relates to a "dry" battery, consisting of a plate of retort-charcoal or other similar substance, non-attackable by acids, a plate of amalgamated zinc, and an exciting paste applied to the charcoal. This paste is composed as follows:—Chloro-mercurate of ammonium, $Hg.Cl^2.N\,H^4Cl$., 10 parts by weight, and chloride of sodium, Na. Cl., 3 parts. The charcoal plate, previously treated with paraffin, is covered with a cake of this paste, and on this cake is applied from five to ten thicknesses of Berzelius' Swedish filtering paper or asbestos soaked in a solution of chloride of zinc at 50deg. Beaumé, and chloride of sodium mixed in equal parts, which solution may also contain a little glycerine.

497. Improvements in Electro-magnets and Armatures, &c., *G. Little, Passaic, New Jersey, U.S.A.*—1*st February*, 1882. 6*d*.

The object of this invention is to obtain the maximum magnetic effect by having the metallic surfaces of the armature and magnets in contact, a rolling motion being given to the armature to avoid sticking between it and the poles. The figure shows how this is done. The magnet is composed of two heads upon a metal tube, with a helix wound between the heads, and each head is divided into poles of a double V-shape as shown in the figure. The armature B is cylindrical. The magnets are charged by the action of a circuit-closing device that admits the current to the helix. The poles are placed so as to operate progressively, that is, as the pole faces of magnet 1 are ceasing to act, the pole faces of magnet 2 come into action, and so on.

513. Improvements in Electric Meters, *C. V. Boys, Oakham.*—2*nd February*, 1882. 6*d*.

This relates to improvements on the inventor's patent No. 4,472, dated 13th October, 1881, for electric meters. According to the present invention a balance is kept oscillating by clockwork, the inventor employing as the spring of this balance a long strip of elastic metal, by which the balance is suspended, the torsion of this strip acting on the balance spring. This spring passes through a long slit in the arm of a lever, which has another arm at right angles to the former, connected to the armature of an electro-magnet in circuit. The armature is drawn in one direction by the attraction of the magnet, and in the opposite direction by an adjustable spring, in such a manner that the slotted arm of the lever takes a position embracing the torsion spring, determined by the current passing through the magnet. The velocity of oscillation of the balance is thus so proportioned to the current, that an index moved by the clockwork which is governed by the balance registers the amount of current passing through the coil in a given time.

538. Improvements in Electrical Accumulators, &c., *W. R. Lake, London.*—3*rd February*, 1882.—(*A communication from J. J. Barrier and F. Tourville de la Vernède, Paris.*)—6*d*.

The plates are formed of a lead ribbon, either smoothed, grooved, or perforated; this ribbon is wound upon itself either in circular, square, or other mode. The layers of the ribbon are separated by cement in which the ribbon is wound whilst in a semi-liquid paste. This paste is composed of one part platinised charcoal, one part litharge or very fine powder, and one part glycerine.

Digitized by Google

SLIP

BRAZILIAN SUBMARINE TELEGRAPH COMPANY. — The traffic receipts of this company for the week ending November 24 amounted to £4,058.

ELECTRIC LIGHTING IN WINNIPEG.—Winnipeg, Manitoba, has now a tramway, and its main street, two miles long, has recently been lighted by electricity.

ELECTRIC LIGHTING AT CANTERBURY.—The Canterbury Poultry Show, to be held this month, will be lighted by the South Eastern Brush Electric Light Company.

ELECTRIC LIGHT IN NEW ORLEANS.—It is stated that the offices of the *Times Democrat* newspaper in New Orleans (U.S.A.) are to be lighted by the Levett-Müller system.

TO BE WOUND UP.—The Electric Works Company, of 3, Bucklersbury, E.C., is to be voluntarily wound up. Mr. W. F. Day, of 79, St. Mark's-square, West Hackney, has been appointed liquidator.

SOUTH AFRICAN TELEGRAPHS.—The revenue of Cape Colony derived from telegraphs during September last amounted to £4,715 17s. 1d., against £4,990 11s. 2d. in 1881, being a decrease of £274 14s. 1d.

SWAN LAMPS.—The Swan United Company are now manufacturing incandescent lamps of 50 and 100 candle-power. The 50 candle-power lamps require an E.M.F. of 50 volts, and the 100 candle-power 100 volts.

ELECTRIC LIGHTING IN AMERICA.—An American paper says:—"Grand Rapids, Mich., has three electric light companies in the field competing for its illumination. There are now 150 electric lamps used in the city."

SHIP STRUCK BY LIGHTNING.—During a severe thunderstorm a few days since the lightning struck the mizzenmast of the steamer "Prussian," at Govan, Glasgow, killing a man named Charles O'Niel, and injuring four others.

RESIGNATION.—Mr. José D. Husbands, of 31, Queen Victoria-street, C., has resigned his position as general manager of the London and Globe Telephone and Maintenance Company (Limited) in order to attend to his private business.

THE LANE-FOX LAMP.—We understand that the directors of the Anglo-American Brush Electric Light Corporation have placed the direction of the Lane-Fox incandescent lamp department, Portpool-lane, in the hands of Mr. St. George Lane-Fox.

THE GULCHER LIGHT.—It is stated that the Gülcher Electric Light and Power Company have orders for supplying electrical plant for lighting the Benares bridge, now being constructed on the Ganges by the Oude and Rohilkund Railway Company.

ELECTRIC LIGHTING AT BURY ST. EDMUNDS.—The Provincial Brush Electric Light Company have been instructed to light up the Corn Hall, Bury St. Edmunds, during the holding of the Blue Ribbon Mission there. The mission is to last for ten days from the 4th December.

THROWING STONES AT TELEGRAPH POSTS.—At the Dewsbury (Yorks.) West Riding Police Court the other day, four boys, residing at Liversedge, paid 10s. each and costs, with an alternative of one month's imprisonment, as the price of a few minutes' stone practice at telegraph poles.

ELECTRIC LIGHT AT SUNDERLAND.—According to a provincial contemporary, Lambton coal drops, near Sunderland, are to be lighted by eight Gülcher arc lamps and some Crookes incandescent lamps. These lights are designed to facilitate the loading of vessels by night and day.

ELECTRIC LIGHT IN LIMERICK.—Messrs. W. J. Shaw and Sons, of Limerick, are about to light up their offices and a portion of their factory with 60 Swan lamps. The current will be obtained from a Bürgin dynamo. The plant is to be supplied and erected by Mr. J. H. Greenhill, of Belfast.

ELECTRIC LIGHTING IN BELFAST.—Mr. J. H. Greenhill, of Belfast, has received an extensive order from Messrs. Harland and Wolff, ship builders of that town, for 11 more Crompton arc lights. They have had four arc lights running most satisfactorily for two months, hence this extension.

CABLE INTERRUPTED.—Information has been received of the interruption of the cable between Jamaica and Porto Rico, cutting off from telegraphic communication all the West India and Panama Company's stations in the West Indies except Jamaica. The company's ships have been ordered to repair the cable.

ELECTRIC LIGHT IN ABERDEEN.—The Brush Electric Light and Power Company of Scotland have contracted to light Castle-street, part of Union-street, Market-street, and Guild-street, Aberdeen, with the Brush arc lamps. Sixteen lamps will be used, which will be placed at a height of 20ft. above the ground.

GAS FIRED BY LIGHTNING.—During a thunderstorm on Friday week a curious occurrence took place at Bridge of Weir Station, Scotland. The lightning entered the signal cabin and ruptured a gas pipe, setting fire to the gas when liberated. The woodwork took fire, but the flames being observed were at once extinguished.

ELECTRIC LIGHTING IN MANCHESTER.—Messrs. G. and R. Dewhurst, one of the leading firms of Manchester, are lighting their warehouses with twelve Pilsen arc lights, 200 incandescent and some Joel semi-incandescent lamps. Messrs. Woodhouse and Rawson have been appointed by the Pilsen, Joel, and General Company, to carry out this work.

ELECTRIC LIGHTING ON THE TYNE.—The Wallsend Slipway Company have for some time past been using Brockie arc lamps to light up portions of their premises. They have within the last few days erected additional lamps of the same kind. The work has been carried out for them by Messrs. Jameson and Schaeffer, of Newcastle-on-Tyne.

ELECTRIC FIRE ALARMS.—The prospectus has been issued of the Electric Fire Alarm and Signals Company, with a capital of £100,000 in £1 shares. The company has been formed to purchase the patents of Sir E. B. Bright and the Exchange Telegraph Company. The temporary offices of the company are at 25, Cockspur-street, Charing-cross, S.W., Mr. R. S. Walker being secretary.

NEW COMPANIES.—The Manhattan District Telegraph Company of New York was incorporated on November 2 with a capital of 100,000dols. The line is to run from a main office in the vicinity of the Stock Exchange to other points in the city where branch offices may be established.—The Olmstead Electric Light and Power Company of New York was incorporated at Albany on November 6, with a capital of 1,000,000dols.

FACTORY BURNT DOWN.—The works of Messrs. Phillips Bros., the well-known makers of electrical apparatus, situated in Macintosh-lane, Homerton, were totally destroyed by fire

Digitized by Google

on Sunday last. We are informed by Messrs. Phillips that, as they have another factory, the Lea Telegraph Works, Hackney Wick, which they started some time since, they hope in about a week's time to be in a position to execute all orders in the usual way.

Institution of Civil Engineers of Ireland.—At the opening meeting of this institution on Wednesday, the 6th December, a paper on "Magneto and Dynamo Electric Machines" will be read by Mr. J. Angelo Fahie, C.E., which will be illustrated by some experiments and numerous diagrams, while a number of incandescent electric lamps will be shown in action. We hope to give some extracts from this paper in a future issue.

Anglo-American Brush Electric Light Corporation.—The following is a copy of a resolution passed by the Board of the above company on the 29th November:—"Resolved, that a call of £3 per share be made on the £4 paid shares of the corporation, to meet the cost of extension of works and machinery and manufacture of stock, the same to be payable in instalments of £1 each on the 1st January, the 1st February, and the 1st March, 1883."

Private Bills.—The number of private Bills to be brought forward in the ensuing Session of Parliament is 253, a decrease of 70 as compared with last year. The total number of applications for Provisional Orders to be made to the Board of Trade is 212. This number exceeds the Provisional Orders applied for last year by 129. The increase is owing to the large number of Provisional Orders relating to the supply of electric light in London and the provinces, of which there are 141.

Underground Telegraphs in France.—The Paris correspondent of the *Standard*, telegraphing on Friday night, November 24, said:—"The inland telegraphic communication of France will, in time, be independent of wind and weather. On Wednesday next (November 29) a number of subterranean lines from Paris will be opened for service, and others will shortly follow. Fifteen millions of francs have already been expended on it, and it is contemplated to expend twelve millions more."

Electric Lighting in Liverpool.—Messrs. Lewis and Co., of Ranelagh-street, Liverpool, have arranged to light up their new premises and warehouses by means of the Pilsen system. They have appointed Messrs. Woodhouse and Rawson, of 11, Queen Victoria-street, E.C., contractors for the work. Fifty Pilsen arc lamps will be used, together with one large arc light of 4,000 candle-power nominal. This is one of the largest, if not the largest installation of arc lights for private purposes that we have heard of.

Professor Palmieri.—Very recently we announced, on the faith of a French contemporary, the death of Professor Palmieri, of the Vesuvius Observatory. Since then we have seen his death recorded in several papers. Within the last few days, however, it has been stated, on the authority of Messrs. Negretti and Zambra, that the professor is in his usual health, and that in all probability the report of his death originated in the fact that his nephew died recently We are very glad to record the fact that Professor Palmieri is still with us, and hope he may have many more years of activity before him.

Swan Lamps and the Russian Government.—We have the best authority for stating that the following paragraph, published a day or two since in the *Daily Telegraph* money article, has no foundation in fact. The paragraph is as follows:—"It is stated that the Swan United Electric Light Company have sold to the Russian Government for £100,000 in cash the exclusive right to use their invention throughout the empire, and to sell their lamps. There can be little doubt that the employment of the electric light in the larger cities and towns of Russia could be made a most lucrative State monopoly. The company's paid-up capital is £160,000, in 80,000 shares, the quotation of which to-day was $2\frac{1}{8}$, $\frac{3}{8}$."

Electric Lighting at Birmingham.—Messrs. R. W. Winfield and Co., of Cambridge-street Works, Birmingham, gave an exhibition of electric lighting early this week in one of their show rooms. The room in question had been arranged as a drawing room, and was lighted by means of a Crompton arc lamp, placed in a large opal glass bowl, supported on a pedestal in the middle of the room, the light from which was reflected on the ceiling, and so diffused throughout the room. The remainder of the works were also lighted by means of Crompton arc and Swan incandescent lamps, the current being generated by Bürgin machines. Mining lamps, table lamps, and brackets and fittings of all kinds, manufactured by Messrs. Winfield, were also shown.

Charing Cross Electric Railway.—Notice has been given of intention to apply for a Bill in the ensuing Session empowering the construction of a railway from Cockspur-street, Charing Cross, near King Charles's statue, and joining the railway authorised by the "Charing Cross and Waterloo Electric Railway Act, 1882;" also another railway forming a junction with the above electric railway, near Belvedere-crescent, and terminating in the parish of Christchurch, Southwark, S.E., near the Blackfriars-road; also other railways in continuation of the above, which will finally terminate close to the Royal Exchange in Cornhill, E.C. The Bill will also authorise the London and South Western Railway Company to contribute towards the cost of constructing the above intended railways.

Electric Light at Birmingham.—The stand of Messrs. Tangye at the Birmingham Cattle and Poultry Show, which was held from the 25th to the 30th November, in Bingley Hall, was lighted by means of Edison lamps, some sixty or seventy of which were used. Two Edison dynamos, one sixty-light, and another fifteen-light, were driven by means of Messrs. Tangye's coupled gas engines of $2\frac{1}{2}$ horse-power. In these engines there are two impulses at each revolution, and consequently steady working is obtained, this being, as everybody knows, of the utmost necessity in incandescent lighting. The lights were erected by Messrs. Smith and Chamberlain, of the Solar Works, Birmingham, who had obtained special permission from the Town Council to do so. This is, we believe, the first time that the Edison light has been shown in Birmingham.

Electric Lighting in London.—The St. Olave's Board of Works will hold a special meeting on the 19th January next to consider the expediency of applying for a license from the Board of Trade to supply electricity. The Board are evidently in no great hurry.—The Lewisham Board of Works, after hearing the report of their delegate to the recent conference of vestries, &c., which was to the effect that local authorities had better apply for licenses, instructed their clerk to "look into the Act."—The General Purposes Committee of the Hackney Board of Works recommend the Board to oppose other companies, but are averse to a provisional order being obtained.—The St. James's (Westminster) Vestry have resolved to apply for a license.—The Bermondsey Vestry have fixed the first Monday in January for the consideration of the question of obtaining a license.

The Telephone on Railways.—The Lancashire and

Digitized by Google

Yorkshire Railway Company are introducing a system of telephonic communication connecting the principal signal boxes been Mirfield and Low Moor, which, when completed, will afford an addition to the block system, &c., for the working of the traffic along the Spen Valley. The instruments are being put in by Messrs. D. Mosley and Sons, of Manchester. This, or a similar means of communication, has been extensively adopted by the company in the Yorkshire district, and has been found to answer the purposes for which it was intended admirably. Some time ago the ordinary telegraphic service, which had been in use on the Cleckheaton branch some time, was removed, and the company recently proposed to again bring it into operation, but after further consideration they decided to introduce the improved means now adopted. Railway companies generally would do well to follow this good example.

Electric Light in Port Elizabeth (South Africa).—A colonial paper of the 18th October says:—"Last Monday night the electric light was exhibited for the first time in Port Elizabeth by the South African 'Brush' Electric Light and Power Company, and we may well congratulate the company, and their efficient electrician on the perfect success of the experiment. Six lamps were lighted—three in Market-square and three on the Hill, near the Port Elizabeth Club—at half-past eight o'clock, and were kept lighted till twelve o'clock. A large concourse of people gathered together at both places to see the novelty, and all were much pleased with the brilliancy of the lights and the steadiness with which they burnt." The lights were to be exhibited for one month. The dynamo was driven by a seven horse-power engine by Hornsby and Sons, of Grantham, Lincolnshire. The lamps, &c., were erected under the superintendence of the company's electrician, Mr. R. L. Cousens.

E.M.F. of a Zinc-Carbon Cell.—According to M. Berthelot, the E.M.F. of a zinc-carbon couple in dilute sulphuric acid is subject to great variations owing to polarisation. When the circuit is first closed, the E.M.F. is greater than that of a Daniell cell in the ratio of 1 to 1·29, but if the circuit be kept closed it rapidly decreases, and at the end of 36 hours is less than half that of a Daniell cell. On interrupting the current the E.M.F. gradually increases, but never regains its primary intensity. If, however, the carbons and porous cells are disconnected, washed with water, and again set in place, then, on closing the circuit, the E.M.F. obtained at first is the same as before. One of these couples, when the circuit is first completed, will not decompose acidulated water, but if a zinc-cadmium couple is added decomposition takes place. Two zinc-carbon couples will decompose potassium sulphate until polarisation has lowered the E.M.F. below that of two Daniell cells.

A Peripatetic Paragraph.—Some time ago (*vide Electrician*, Vol. VI., p. 216, March 19, 1881) we published an illustration, with short description, of the longest span of wire in the world, viz., that over the River Kistnah, between Bezorah and Sectanagrum, in India, which is more than 6,000ft. across. Our information and illustration were derived from private sources. Since that time we have come across our illustration and letterpress in various shapes and guises; sometimes the letterpress without the illustration, sometimes both together, but never with the source acknowledged. The whole is now reduced to a convenient little paragraph, which has helped several printers and sub-editors to fill up a column. Thus we have seen it in the *Journal* of the Franklin Institute, *Scientific American* (more than once), *Operator*, *Journal of the Telegraph*, *La Lumière Electrique*, *L'Electricité*, *L'Electricien*, *Engineer*, several provincial papers, &c. After this list we think we are justified in the use of the word "peripatetic."

Long Distance Telephoning.—A novel experiment is now in progress with a view to overcoming the difficulties attendant upon long-distance talking. 'Between Boston and Worcester (U.S.A.) a line is being constructed of No. 4 gauge wire, which reduces the telephone distance between the two cities about one-half. This line, says the *Scientific American*, will cost 10,000 dollars, whereas an ordinary line of No. 9 wire would cost only about 4,000 dollars. If the experiment is a success, the line will be extended to Springfield, and similar lines will be built from Boston to Portland, Plymouth, N.H., and other distant points, enabling subscribers there to talk with Boston as readily as subscribers in Lowell, Salem, Lawrence, and other neighbouring places. The ordinary telephone line, running straight across the country, costs from 100 dollars to 150 dollars per mile. The big wire is now completed between Boston and Hopkinton, a distance of twenty miles. Communication over the line on this twenty-mile stretch is as distinct as in the city.

The Telegraph Construction and Maintenance Company.—Notification is given that application will be made next Session on behalf of the Telegraph Construction and Maintenance Company for an Act for the removal of doubts as to the meaning of the company's Memorandum of Association, dated April 6, 1864, to extend the objects for which the company was established, and to include amongst those objects the construction, laying down, maintenance, purchasing, hiring, letting, selling, working, and use of works and apparatus for the production and use of electric and magnetic or any other force for any purpose whatsoever; and the purchase, importation, manufacture, and sale of all materials, articles, and things in any way used or connected with the production, transmission, and use of electric and magnetic or any other force. Authority will also be asked in the Act to confer upon the company all such powers, rights, and privileges as may be necessary or expedient for effecting these objects, and to vary and extinguish all rights and privileges which would in any way interfere with the objects of the Bill, and to confer other rights and privileges.

The Lighting of the Law Courts.—The daily papers have told us that the ceremony of opening the law courts is to take place on Monday next. It is not, perhaps, so generally known that great efforts are being made to have all the arrangements connected with the experimental electric lighting ready for that day. Such, however, is the case, and we have been astonished at the rapidity with which the work is being carried on. Messrs. R. E. Crompton and Co. have the work in hand, and by the time these lines are read, the engine, a 20 horse-power compound, by Marshall and Sons the counter-shafting, the dynamos, and the wires will be mostly in their places. Three courts are to be lighted by Swan lamps. The fittings have been specially designed for each court. They have been constructed by Messrs. Winfield and Co., of Birmingham. Besides the three courts, some of the corridors will be lighted by similar lamps. Altogether about 150 incandescent lamps will be used, and six arc lamps. The arc lamps are, we believe, of a new pattern. It is said that a trial will be made of the FitzGerald-Crompton secondary battery at this installation. Next week we shall be able to describe the whole of the arrangements. Meanwhile, so far as we can judge, the work is being carried out in a very able manner, and we have no doubt the result will be satisfactory.

Electric Lighting in the Country.—The Canterbury Town Council have resolved to apply to the South Eastern

Digitized by Google

Brush Electric Light Company and other companies with the object of ascertaining upon what conditions they would act with the Town Council in the event of the latter obtaining a license to supply the electric light. The West Hartlepool Improvement Commissioners think that, as no independent company has yet given evidence of their intention to apply for an order to supply electricity in that town, that they, the Commissioners, had better "bide a wee," at all events for the present. The Stockton Town Council, being in the same case, are of the same opinion. The Luton (Bedfordshire) Town Council have resolved not to apply for an order at present, but will send a deputation to Mr. Chamberlain, "asking (*inter alia*) that, if possible, no order should be granted for twelve months, that the term of any order or license granted to a company should not exceed twelve or fourteen years, and that a clause should be inserted empowering the council to purchase the plant and property of the company at the end of such term, without any payment for goodwill." The Pemberton (Lancashire) Local Board will not apply for an order. The Stourbridge (Worcestershire) Improvement Commissioners will oppose outside companies. The Salford Town Council, "in the present uncertain state of electric lighting," will not apply for an order, but the Newcastle-on-Tyne Town Council are of a different opinion, and will obtain an order.

Incandescent Lamps and Photography.—According to Mr. T. Bolas, a 5-candle Swan incandescent lamp can be maintained at any required temperature, from a low red heat up to the volatilisation point, by slightly modifying an ordinary Gramme machine, thus affording a ready means of obtaining sufficient light to take a photograph in from two to three seconds. To obtain this result, a small electro-magnet is arranged as a keeper over the jaw pieces surrounding the revolving armature in a Gramme machine, so as to form consequent poles with those of the field magnet, the circuit being completed through the subsidiary electro-magnet and the incandescent lamp. The subsidiary electro-magnet placed in this position gives the machine a character intermediate between a magneto and a dynamo machine. When the armature is caused to rotate, and the external circuit is left open, a considerable difference of potential arises between the poles, although not so great as it would have been if the soft iron core of the electro-magnet were not there acting as a keeper to the field magnet. This potential is sufficient to insure the efficient action of the machine even when a very high resistance is included in the external circuit. When a 5-candle Swan lamp is placed in circuit, and the machine is turned with one hand at full speed, the lamp is almost immediately destroyed; but by regulating the speed any required temperature may be maintained, from a low red-heat upwards, a light of from 200 to 300 candles being readily attained. Of course, the lamp is soon destroyed, but as it is used only for a few seconds each time, from fifteen to twenty portraits can be taken before that occurs.

Provisional Orders.—The following additional notices of intention to apply for provisional orders empowering the supply of electricity for lighting and other purposes have been made public:—The Metropolitan Brush Electric Light and Power Company have given such notices with reference to the following London districts, viz.: Strand, Camberwell and Penge, St. George's (Hanover-square), St. James's (Westminster) and St. Anne's (Soho), Kensington and St. Margaret's (Westminster), St. George's-in-the-East, Mile End Old Town, Whitechapel, Limehouse and Poplar, Lambeth, St. Giles and St. George's (Bloomsbury), Holborn, Chelsea, St. Martin's-in-the-Fields, and Westminster, St. Marylebone, and Paddington. The Provincial Brush Electric Light and Power Company have also given a similar notice with regard to Sudbury. The Union Electric Light and Power Company of St. Stephen's-chambers, Telegraph-street, E.C. (an offshoot of the Pilsen, Joel, and General Company) will endeavour to obtain powers for Southampton, Plymouth, Devonport and East Stonehouse, Bradford (Yorkshire), Rochdale, Chester, and Exeter. Messrs. Ferranti, Thomson, and Ince, 3, Fenchurch-avenue, E.C., have given notice as regards Chelsea and Hampstead, in London. The following Corporations notify their intention to supply their own districts if they can obtain orders, viz.: Darlington, Blackburn, Scarborough, Beccles (Suffolk), Rochdale, Grantham (Lincolnshire), Over Darwen (Lancashire), Winchester, Leicester, South Shields (Durham), Carlisle, and Halifax. The following local authorities will do likewise, viz.: Malvern (Worcestershire), Folkestone (Kent), Pudsey (Yorkshire), and Wallasey (Cheshire).

Electrolysis of Hydrogen Peroxide.—A dilute solution (three grains per litre) of hydrogen peroxide undergoes electrolysis in two different ways. With sufficiently high electromotive force, oxygen and hydrogen are given off at the two electrodes, but with low electromotive force, such as that of a zinc-cadmium couple, only oxygen is given off, and no hydrogen is evolved at the negative electrode. Under these circumstances electrolysis resembles the spontaneous decomposition of the peroxide, but is accelerated by the action of the current. Either the hydrogen peroxide splits up into oxygen and water, or, more probably, a secondary reaction takes place, and the electrolysed hydrogen combines with undecomposed hydrogen peroxide, forming two molecules of water, thus, $H_2 + H_2O_2 = 2\,H_2O$. The final result, $2\,H_2O_2 = 2\,H_2O + O_2$, is exothermic, and develops + 43·6 cals., for $H_2O_2 = H_2 + O_2$ absorbs − 47·4 cals., and $H_2 + H_2O_2 = 2\,H_2O$ develops + 90·6 cals. This form of electrolysis can consequently be effected by any electromotive force, however feeble. When the electromotive force is equal to that of a Daniell cell, hydrogen is given off as well as oxygen, and the simultaneous evolution increases as the electromotive force increases. The electromotive force of a Daniell cell is the result of a reaction which develops + 49 cals., a quantity slightly higher than that absorbed by the decomposition of the hydrogen peroxide into its elements. The peroxide may possibly first split up into oxygen and water, the latter then undergoing electrolysis, but in this, as in all cases of electrolysis, only the initial and final conditions enter in the calculation of the minimum electromotive force required. For the same reason the presence of dilute acid does not interfere with the result. That both modes of electrolysis may take place simultaneously, as the author has already found in the case of ferrous and manganous sulphates (*Comptes Rendus*, 93, 760) is shown by the variations in the relative proportions of the oxygen and hydrogen evolved. With higher electromotive force sufficient to decompose water the decomposition becomes complex, and the ratio of hydrogen to oxygen evolved is increased in consequence of the electrolysis of the water present.—Abstract of Paper by M. Berthelot in *Comptes Rendus*, 95, 8—11, published in Chemical Society's *Journal* for November.

The Danger of Overhead Telegraph Wires.—On Wednesday afternoon a deputation from the Westminster District Board of Works waited in the Conference Room, House of Commons, on the members for Westminster, Mr. W. H. Smith and Lord Algernon Percy, with respect to the danger to life created by the increased number of telegraph

Digitized by Google

and telephone wires which were being stretched across the thoroughfares.—Mr. Reynolds Yorke, M.P., having introduced the deputation, Mr. Horn said they wished to point out the great danger arising from the increased number of telegraph and telephone wires in their district. While the Government had done their best to remove these wires, which were dangerous to the public and detrimental to the beauty of their city, many companies had sprung up and were straining wires across the thoroughfares. It had been stated that the Board were liable for any damages caused by this, but they had no control in the matter.—Mr. W. H. Smith said he thought that, as a nuisance authority, the Board might give notice to the companies to remove the wires as being dangerous to the public safety.—Mr. Harris, clerk to the Board, thought they might, for the straining of a wire from one point to another across the street was very different from the erection of a post on a house.—Mr. W. H. Smith said that last session the Attorney-General said the local authorities had the power, and were responsible.—Mr. Horn: They are responsible, without having the power.—Lord A. Percy said the Postmaster-General stated that only nineteen miles of wires had been put up within the past year, and the tone of his answer to a question was that the Government had no power to stop the erection of further wires.—Mr. W. H. Smith thought the question was whether the Board had the power to interfere with the wires. They could prevent a pipe or a bridge being put across the street, and this was a pretty similar case.—Mr. White said the matter was urgent, as the board would be held responsible for loss of life.—Mr. W. H. Smith: Then you must have power to prevent it.—Mr. Yorke, M.P., suggested that the Local Government Board should be asked if such power existed in the local board.—Mr. W. H. Smith advised the deputation to act on his hon. friend's suggestion. If the answer of the Local Government Board was in the negative, then he should concert with his colleague (Lord Percy) what measure was best to be taken.

Measuring Changes of Temperature by Thermo-Electricity.—The following account of the arrangements and apparatus used in some experiments made by Professors Marshall and Smith and Mr. Omond to determine the lowering of the maximum density point of water by pressure is taken from the *Proceedings* of the Royal Society of Edinburgh, Session 1881-82, No. III:—"The changes of temperature which followed changes of pressure were measured by thermo-electricity. One junction of a thermo-electric circuit of very fine copper and iron wire was placed inside the gun (a strong iron vessel used in connection with a powerful force pump for producing the compression), the wires passing out between two discs of leather well soaked in oil near the bottom, which could be taken off. The others were soldered to thick copper wires in connection with a dead-beat reflecting galvanometer, and placed in a vessel of water, which was kept at as uniform a temperature as possible, one of them being put into a test tube to prevent the slight voltaic action which disturbed us in our earliest experiments. As we had in some of our experiments to measure extremely small changes of temperature, the galvanometer was made very sensitive by the controlling magnets, and the deflections read on a scale about $2\frac{1}{2}$ metres from the galvanometer. We were enabled in this way to measure as small a change of temperature as $\frac{1}{300}$° C, even with a single thermo-electric pair. However, any change in the electric field was at once felt. The rooms we worked in were on the ground flat, looking into Chambers-street, and every passing vehicle, on account of its iron fittings, disturbed us. The reader of the galvanometer scale, who was in a darkened room by himself, could generally tell the direction in which a vehicle was moving from the motion of the image on the scale, and on once crying out that a man walking past affected the galvanometer, the experimeter at the pump immediately rejoined that he was carrying some iron on his back. To avoid this change of the magnetic field, we took one set of observations at midnight. As it was generally impossible to determine directly with a thermometer the temperature of the junction inside the gun, to enable us to interpret the galvanometer readings, there was an extra thermo-electric circuit, as nearly as possible the same as that connected with the gun, whose junctions were in vessels of water, so that the temperatures could be directly read with a thermometer, and altered at pleasure. Any change in the sensitiveness of the galvanometer was each day detected by this arrangement."

The Dangers of Electric Lighting.—In the Mill mutual insurance companies in New England there were sixty-one establishments lighted by electricity up to last May. With few exceptions the lights had not been in use previous to the fall of 1881, and many had been started early in the spring. In these sixty-one establishments Mr. C. J. H. Woodbury records twenty-two fires due to electric lighting, and assignable to the following causes: Eight were from globules of melted copper or particles of hot carbon falling out from the bottom of the globes. The actual number of fires from this cause was probably many times this number. This class of fires will not continue to happen, as all makers now set their lamp globes in a tight stand with a ridge around the edge. A flat plate will not answer the purpose, as there was one instance where drops of melted copper rolled off and started a fire. Four fires were due to leaking water or washing floors, and two more were caused by water in a dye-house condensing on the building to which uninsulated wires were fastened. In most of these instances a grounded circuit formed one of the two connections necessary to divert the electricity from the wires. Many of the lower carbons fell from lamps, and five fires were caused where they fell upon combustible material. Three fires were caused by cross-arcs from one wire to another, where uninsulated wires were fastened against conductors. In one instance the conductor was formed by dust settling upon uninsulated wires, and on a damp day it absorbed enough moisture to form a path for the formation of a cross-arc, which started a slight fire. In another instance the wires were fastened to a damp beam, which was decayed, and was burned nearly in two by the smouldering fire. And in a third instance damp brickwork in a tunnel was a sufficient conductor to establish an arc, which did not do any material damage there, but injured the dynamo. Two fires were caused by improper switches; two by water reaching the wires of a circuit already grounded; and one from wires coming in contact with a building, so that their insulation was worn away. Electricity forms the safest method of illumination when the following precautions are observed:—The system insulated throughout, so that there is no electrical communication with the earth, or from one part of the apparatus to another, except through the proper conductors, even if the wires should be exposed to water; all switches made with lapping connection, so that no arc can be formed; arc lamps provided with globes closed underneath, and the frame so arranged that the lower carbon could not fall out, even if the clamp failed to hold it securely; the wires of incandescent systems provided with a sufficient number of fusible links to secure the system against any damage from an excess of current.

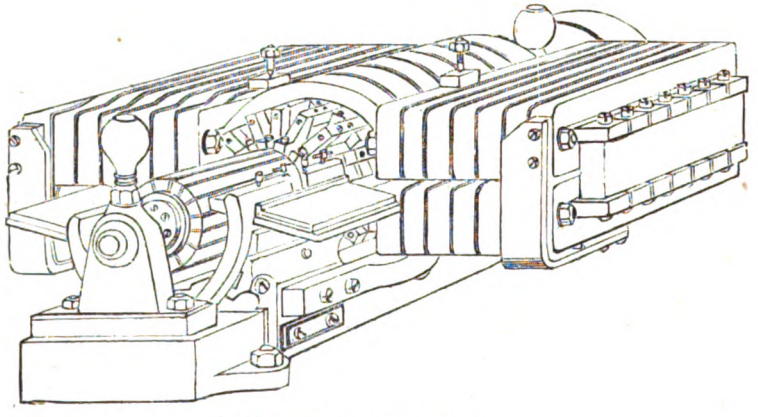
THE MUNICH EXHIBITION.—IV.

Our last paper concluded with a description of the modification in the Crompton arc lamp as exhibited at Munich. We stated that one Bürgin dynamo was used to supply the current for Maxim or Swan lamps. The Maxim lamp was that of the ordinary type, while the Swan was a new 40-candle lamp not, so far as we know, previously exhibited. For many months we have been experimenting with Maxim and Swan lamps, and often have brilliantly lighted the room in which we are now writing with one Maxim lamp. The room is similar to those in numbers of suburban houses, about the dimensions 16ft. by 12ft. by 9ft—that is about 1,700 cubic feet. We run the Maxim lamp at about 50 candles, and think at that power they will be found economical. Experimental work is, as a rule, not good for length of life, but so far the Maxims have a length of life equal to that of any other lamp. The Maxim lamps at Munich were used to illumine a room filled with antique furniture. The Swan lamps, as we have said, were of a new type, to give a normal candle-power of 40 candles. The resistance of these lamps is about 70 ohms hot, and they require an E.M.F. of about 90 volts, thus getting a current through the carbons, $C = \frac{E}{R} = \frac{90}{70} = 1{\cdot}3$ ampere nearly. The horse-power absorbed by each lamp is known from the equation $\frac{C \cdot E}{746}$, which in this case gives

$$\frac{1{\cdot}3 \times 90}{746} = \frac{117}{746},$$

so that from 6 to 7 such lamps may be expected to be obtained by the expenditure of one horse-power in the carbons—say six, and this gives about 240 candles per horse-power, a good result. The arrangements regarding the exhibits of Messrs. Crompton and Co. were carried out by Mr. Bollinger, of Milan, the agent of this firm. Our thanks, and those of many another visitor, are due to Mr. Bollinger for his assistance in pointing out all that was worth seeing at the Munich Exhibition.



Siemens' Depositing Dynamo.

The great firm of Siemens and Halske did not exhibit directly at Munich, but one of their agents, M. Riedinger, exhibited machines and lamps of the ordinary construction.

Some latitude being allowable in a report, a brief reference to a machine exhibited at Paris, but, so far as we know, not yet illustrated in an English paper, may be permitted here. This machine is of the type used for depositing metals, and is therefore made to give quantity and not intensity. It will be seen from the figure that the coils of the field magnets are really discs of copper an inch or so in thickness, similarly the armature coils are really bars of copper. Machines of this type are employed at the works at Öker, as we have said, to deposit copper. We remember that slabs of the deposited copper were exhibited at Paris, and had hoped to have seen similar exhibits at Munich. The machines of the Siemens make exhibited at Munich were the ordinary direct and alternate current machines, well known and extensively used both with arc and incandescent lamps. There are many people who maintain that the length of life of an incandescent lamp is increased by using an alternate current machine, and Siemens machines of this type are frequently used with Swan lamps.

An interesting exhibit was that of M. L. Weiller, whose representatives in Great Britain are the Phosphor-Bronze Co. The wires exhibited were some of phosphor-bronze, which is a new alloy that is said to give exceedingly favourable results. These wires were referred to by Mr. Preece in his address to the Society of Telegraph Engineers, and the following tables, showing their properties, have been published by our contemporary *Engineering*. These tables will save us from any further remarks, as they tell the whole value of the wire:—

I.—*Table showing Properties of Silicious Bronze Wires.*

Nature of Wire.	Diameter.		Electrical Resistance per Kilometre.	Resistance Kilogs.	Conductibility Compared with Copper.	Resistance to Rupture. Tons per Square inch.
	mm.	in.	ohms.			
Copper	1	.04	20.36	21.8	100	12.3
Telephone phosphor-bronze wire	1	.04	70	70	29.3	56.3
Telephone silicious bronze wire	1.08	.042	48	80	36	56.3
Telegraph silicious bronze wire	1.30	.051	12.13	67	97	32.1
Silicious bronze wire covered with magnetic oxide for telegraph lines, in the vicinity of the sea, and at railway stations	1.50	.06	9.7	91	93	33
Telegraph silicious bronze wire	1.70	.067	8.6	137	82	38
Telegraph silicious bronze wire	1.94	.076	5.8	140	93	33

If we take as a type of telephone conductor the wire 1 mm. in diameter, and as a type of telegraph line the wire 2 mm. in diameter, the comparison with wires in ordinary use will be as in the following Table:

II.—*Comparison of Phosphor and Silicious Bronze with Iron and Copper Wires.*

Nature of Wire.	Resistance to Rupture.	Electrical Resistance per Kilo.	Conductibility Compared with Copper =100.	Resistance to Rupture.
I. *Telephone Wires* 1 *mm. dia.:*	kilo.	ohms.		tons per sq. in.
Silicious bronze, Weiller	70	56	36	56.3
Phosphor-bronze, Weiller	70	70	29.3	56.3
Phosphor-bronze, Montefiore	59	107	19	48
Swedish Iron	28	135	15.8	22.7
Siemens-Martin steel	32	166.8	13.3	26.5
Pure copper	21.8	20.57	100	12.3
II. *Telegraph Wires* 2 *mm. dia.:*				
Silicious bronze, Weiller	157	5.1	97	33
Phosphor-bronze, Weiller	138	6.4	76	27.9
Swedish iron	113	33.8	15.8	22.7
Siemens steel	132	41.7	13.3	26.5
Pure copper	87	5	100	12.3

III.—*Weight of Different Telegraph Wires of Equal Conductivity.*

—	Diameter.	Resistance.	Weight per Mile.
	mm.	ohms.	lb.
Silicious bronze	2	5.1	88.5
Phosphor-bronze	2.13	5.1	110.8
Swedish iron	5.10	5.1	584
Siemens steel	5.70	5.1	931

CONNECTED GENERAL THEOREMS IN ELECTRICITY AND MAGNETISM.

BY OLIVER HEAVISIDE.

In mathematical investigations relating to electro-magnetism, it often happens that the equations assume such a very complex form that the real meaning of the relations expressed by them becomes hidden away, as it were, beneath a tangled mass of x, y, z's, and can only be recognised by groping about from one equation to another, comparing them, selecting certain equations as important, rejecting others as needless, and, finally, from the few selected main equations, serving as successive stepping-stones, determining the essential nature of the relations under investigation. That there are so many quantities involved in electro-magnetism is one reason for this complexity and obscurity, but it is immensely increased by the circumstance that they are usually vectors, or directed quantities, requiring three specifications, instead of the one which is sufficient for a scalar quantity; and from the ordinary $x\,y\,z$ system only recognising magnitudes, so that a set of three equations is required to fully exhibit a single relation between a pair of vectors. Thus we may say, in words, that the current is the curl of the magnetic force, but if we have to express this symbolically we require three equations, which express the same thing for the components in three rectangular directions.

A very remarkable system of mathematics was invented by Sir W. Hamilton, called quaternions, which may be described as the calculus of vectors. Owing to the universal presence of vectors in physical science, it is exactly fitted to express physical relations. Instead of breaking up vectors into three components, working upon them as scalars, and then, when required, compounding them again to get back to vectors (a most roundabout method) in the calculus of vectors we may fix our attention upon the vectors themselves, and work upon them direct. One equation takes the place of three. Investigations are greatly shortened. The real relations between the quantities are not lost sight of, and this again serves to annihilate a lot of useless work that might be done in the scalar system owing to obscurity.

The calculus of quaternions ought then, one would say, to speedily supplant the ordinary methods in physical applications; in fact, it should have done so already. But it has not. Does this arise from mere Conservatism—the hatred of having to leave the old ways, even for better? Although this may be partly true, it cannot be the whole truth. Against the above stated great advantages of quaternions has to be set the fact that the operations met with are much more difficult than the corresponding ones in the ordinary system, so that the saving of labour is, in a great measure, imaginary. There is much more thinking to be done, for the mind has to do what in scalar algebra is done almost mechanically. At the same time, when working vectors by the scalar system, there is great advantage to be found in continually bearing in mind the fundamental ideas of the vector system. Make a compromise; look behind the easily-managed but complex scalar equations, and see the single vector one behind them, expressing the real thing.

An easily-grasped example of the importance of considering the vector itself may be here given. In a field of electric force, what relation does the total amount of force passing outward through a completely closed surface bear to the amount of free electricitiy enclosed by it? Consider a single charge e within the surface. By definition, the electric force is radial, of strength $e \div r^2$ at distance r; and since $4\pi r^2$ is the area of the spherical surface of radius r, the total force through it is $(e \div r^2) \times 4\pi r^2 = 4\pi e$. This is perfectly clear when the closed surface is that of a sphere, and the charge is at its centre. But put the charge at some other part of the enclosed space. The force is now of different strength at different parts of the surface; and, moreover, it does not go straight through, perpendicular to it, and it is quite a complex matter to sum up the total force by algebraical methods. But if we fix our attention upon the system of force, which we may do by imagining a set of equally-distributed radial lines drawn from the charge, inseparably connected with it, we see at once that the same amount of force as before, viz., $4\pi e$, goes through the spherical surface at whatever part of the enclosed space the charge may be placed, just as the same amount of light would come from a candle substituted for the charge; and, moreover, that the same is exactly true for any other closed surface, however complex its form may be, and however many times a radius drawn from the charge cuts the surface before finally emerging never to enter again. The only essential thing is that the surface must *enclose* the charge. Now this being true for one charge, is true for any number, so that the total amount of force passing out through a closed surface is always $4\pi \times$ total charge within, however it may be distributed.

[If the surface be unclosed, we may, in the case of a single charge, substitute for it a portion of a spherical surface bounded by the same lines of force, whence it follows that the amount of force passing through the unclosed surface is $4\pi e \times$ ratio of area of the portion of spherical surface to the whole, *i.e.*, $e \times$ solid angle subtended at e by the line bounding the unclosed surface, by the definition of a solid angle.]

An immediate consequence is that the electric force at the surface of a charged conductor is $4\pi\sigma$, where σ is the surface density. For, by the foregoing, $4\pi\sigma$ is the amount of force coming from unit of area of the surface. Now there is no force within the surface, otherwise there could not be equilibrium, therefore $4\pi\sigma$ is the external force; it is perpendicular to the surface, because if it were not, there would be force along the surface, which is against equilibrium again.

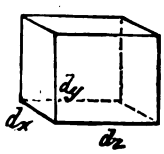
Besides the complexity above referred to, there is in general working a frequent repetition of the same succession of operations in different places. These operations may themselves be of a complex nature; yet, if they are carried out in one investigation, the results may be transferred to another, perhaps relating to a quite different matter. Hence the utility of general theorems. The three allied theorems which we will now discuss are of great assistance in electricity and magnetism. Analytical proofs of them may be, and are given, which are only to be followed with some difficulty, especially as regards No. II. below; one I have seen in a German work of No. I., which is comparatively simple, was about six pages long. This is by no means necessary, for without losing the character of exactness, the demonstrations may be given in words, although in the final expression of the theorems symbols are desirable.

I. The first theorem relates to the surface-integral of a vector over a closed surface, and we require to substitute for it a volume-integral taken throughout the enclosed space. We have already had one example of this, *viz.*, for electric force; the quantity integrated throughout the space being $4\pi\rho$, where ρ is the volume-density of electricity. We now require it in a more general form, applicable to any vector. But, to fix ideas, we may conveniently think of electric force. What we really require is the excess of the amount of force leaving the surface at some places over that entering it at other places. We may go all over the surface, dividing it into little bits, find the flow through each little bit, and add the results together. If R is the force, dS an element of surface, ϵ the angle between R and the normal outwards, the force through dS is R$\cos\epsilon\, d$S, and the surface-integral is $\iint \mathrm{R}\cos\epsilon\, d\mathrm{S}$ over the whole surface. We now require to express this in the form of a volume-integral taken throughout the enclosed space. In the first place, we may easily prove that this is capable of being done. For divide the volume V into two parts, V_1 and V_2. The act of division creates a fresh surface, or, rather, a pair of twin surfaces, born at identically the same moment, like + and − electricity. Now consider the integrals over the two complete surfaces of V_1 and V_2. The surface-integral over V_1 consists of the integral over that portion of the surface of V which the piece V_1 possesses, and of the integral over the new surface, one of the twins. Similarly, the integral over surface of V_2 consists of the integral over the other portion of the surface of V, and of the integral for the other twin. Now regard only the twin surfaces. Put the surfaces together, so as to get the original volume; the two integrals are exactly equal, for the surfaces coincide, and they

Digitized by Google

are reckoned in opposite directions; therefore, by addition, they cancel. [The case of discontinuity in the force within the volume V is here excepted.] Therefore, the integral over the closed surface of V equals the sum of the two surface-integrals over the complete surfaces of the two pieces V_1 and V_2 into which we divided V. The same thing is obviously true if we divide each of our two volumes into two more; the original integral now equals the sum of the four complete surface-integrals, the newly created twin integrals always cancelling when taken together. And since this may be carried on to any extent, we may divide the volume V into an indefinitely great number of elements, each $= d\,V$, and our surface-integral is exactly equal to the sum of all the surface-integrals outwards over the complete surfaces of all the elementary volumes. Thus the volume-integral is possible; and further, we know what the element of the volume-integral is. It is the integral of force outward over the surface of the element of volume.

It now only remains to put this element of the volume-integral into a symbolical form in terms of the force. Let the element of volume be a cube, edges dx, dy, and dz. Let X, Y, Z be the components of R at the corner where dx, dy, and dz meet. The amount of force leaving the cube is the sum of the six amounts leaving it through the six plane faces; each of these is force × surface, therefore they are



$$-X\,dy\,dz \text{ and } \left(X + \frac{dX}{dx}\,dx\right) dy\,dz;$$

$$-Y\,dz\,dx \text{ and } \left(Y + \frac{dY}{dy}\,dy\right) dz\,dx;$$

$$-Z\,dx\,dy \text{ and } \left(Z + \frac{dZ}{dz}\,dz\right) dx\,dy;$$

Adding these together, we get

$$\left(\frac{dX}{dx} + \frac{dY}{dy} + \frac{dZ}{dz}\right) d\,V,$$

where $d\,V = dx\,dy\,dz$, the element of volume. This is the element of the volume-integral; consequently we have

$$\iint R\cos\epsilon\,dS = \iiint\left(\frac{dX}{dx} + \frac{dY}{dy} + \frac{dZ}{dz}\right) d\,V \quad . \quad . \quad . \quad (I.)$$

for the complete expression of the theorem. The left side is the integral of R over the surface of V; the right side is the equivalent volume-integral, to be extended throughout V.

Although we have spoken of force, it is true for any vector. If R is the velocity of an incompressible fluid at any point, and X, Y, Z its components, then, since the same quantity of fluid must enter as leaves any closed surface, the surface-integral is *nil*, and

$$\frac{dX}{dx} + \frac{dY}{dy} + \frac{dZ}{dz} = 0$$

is true everywhere. This is the equation of continuity. If R is current density, the same equation is true. If R is electric force, the same equation applies wherever there is no free electricity.

Where there is free electricity, let ρ be the volume-density, then $\rho\,d\,V$ is the amount within the element of volume $d\,V$. We know that 4π times this is the surface-integral of force over the element. Consequently,

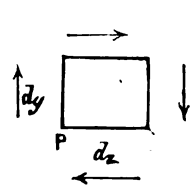
$$4\pi\rho\,d\,V = \left(\frac{dX}{dx} + \frac{dY}{dy} + \frac{dZ}{dz}\right) d\,V,$$

or

$$4\pi\rho = \frac{dX}{dx} + \frac{dY}{dy} + \frac{dZ}{dz};$$

which is the general relation between electric force and electrification. Now, when ρ is −, lines of force converge to the element, whence $-\left(\frac{dX}{dx} + \frac{dY}{dy} + \frac{dZ}{dz}\right)$ is called the "convergence" of the vector R. Electric force has no convergence save where there is free electricity; on the other hand, electric currents have no convergence *anywhere*, neither has their magnetic force, nor their vector-potential, nor any of the quantities considered in Article II. on "Magnetic Force and Current."

II. We now come to unclosed surfaces, or surfaces bounded by a closed curve. If we take any closed curve, then, by Theorem I., the surface-integral of electric force over any two surfaces bounded by the curve is the same, provided there be no free electricity between them, the integrals being reckoned in the same direction through the curve. And this is true for any vector-quantity which has no convergence. The surface-integral thus depends on the form of the bounding curve only, and we may naturally expect that it can be put in the form of a line-integral taken round the curve. But it is convenient for the demonstration to commence with the line-integral. Let R be any vector, which we may now consider as magnetic force; the line-integral of R once round the closed curve is then the amount of work done by the magnetic force on a unit magnetic pole when it is caused to move once round the curve. If ds is an element of the curve, the work for the path ds is ds × component of force along ds, or $R\cos\epsilon\,ds$, where ϵ is the angle between R and ds; consequently, the line-integral is expressed by $\int R\cos\epsilon\,ds$. We require now to express this in the form of an equivalent surface-integral of another vector over any surface bounded by the curve, and to find what relation the new vector bears to R. The proof that the surface-integral is always possible is easy. Imagine any surface S bounded by the closed curve. As in the first theorem we divided the volume we started with into two, so now we divide the surface S into two, S_1 and S_2, by means of a line joining any two points of the boundary of S. We thus form two closed curves, each having the new line in common. Now reckon the line-integral of force once round both of the closed curves, rotating the same way. In going round the first we move one way along the common path, and in going round the second we move the other way; therefore, the sum of the two integrals is equal to that round the original closed curve, for the integrals for the common portion cancel when added. This device, which is due to Ampère, may be naturally extended. Divide the whole area S into an indefinitely great number of elements, dS; find the line-integral round every element, add together all the results, and the sum is equal to the line-integral once round the bounding curve of S, owing to all the inner line-integrals cancelling. The direction of rotation must, of course, be the same for every element of surface. The elementary part of the equivalent surface-integral is, therefore, nothing more than the line integral of R round an element of surface. To find the exact relation between this and R, it is best to suppose in the first place that the surface S is made up entirely of plane portions, all of which are either parallel to the planes of $y\,z$, or of $z\,x$, or of $x\,y$. Take an element parallel to the plane of $y\,z$, axis along x. The + direction of rotation is right-handed, and the + direction of x downwards through the paper. Now, X, Y, Z being the components of R at the corner P, we have nothing to do with the component X, because it is at right angles to the closed curve. The integrals for the four sides of the square are, starting from P,



$$Y\,dy;\ \left(Z + \frac{dZ}{dy}\,dy\right) dz;\ -\left(Y + \frac{dY}{dz}\,dz\right) dy;\ -Z\,dz.$$

Adding these all together we get simply

$$\left(\frac{dZ}{dy} - \frac{dY}{dz}\right) dy\,dz = X_1\,d\,y\,d\,z, \text{ say.}$$

Similarly, the line-integrals round elements of surface $dz\,dx$ and $dx\,dy$ are

$$\left(\frac{dX}{dz} - \frac{dZ}{dx}\right) dz\,dx \text{ and } \left(\frac{dY}{dx} - \frac{dX}{dy}\right) dx\,dy$$
$$= Y_1\,dz\,dx, \text{ say.} \qquad = Z_1\,dx\,dy, \text{ say.}$$

If, then, we assume X_1, Y_1, Z_1 to be the components of a

Digitized by Google

new vector R_1, we have line-integral of R = surface-integral of R_1, provided that the surface is made up as above stated.

But if we diffentiate the three components of R_1 to x, y and z, and then add, we find

$$\frac{d X_1}{d x} + \frac{d Y_1}{d y} + \frac{d Z_1}{d z} = 0,$$

which shows that the new vector has no convergence anywhere, and consequently its surface-integral over *any* surface bounded by the closed curve is the same. Consequently, the theorem (Stoke's) is proved for any surface. We may write it simply

$$\int R \cos \epsilon \, d s = \int\int R_1 \cos \epsilon_1 \, d S \quad . \quad . \quad . \quad (II.)$$

The left side being the line-integral of R, the right the surface-integral of R_1, ϵ the angle between R and the element of curve $d s$, ϵ_1 the angle between R_1 and the normal to the surface-element $d S$; and the relation between the components of R_1 and those of R being those above given.

If R is magnetic force, R_1 is $4\pi \times$ current-density.

If R is the vector-potential of current, R_1 is magnetic force. And, in general, R_1 is the curl of R.

III. There is yet one more connected theorem, which relates to *un*closed curves. If a vector, R, has no curl, the line-integral once round any closed curve is zero, by the last theorem. Such a vector is electric force. Taking, then, two points A and Z on the closed curve, the line-integral of R from A to Z by one path is cancelled by that from Z to A by another; or the line-integral of R from A to Z is the same along any path; it therefore depends only upon the *position* of A and Z, the common terminations of the paths. Let, then, at every point of space the value of a scalar quantity P be given, its values at A and Z being P_A and P_Z, and similarily for any other point. Divide any line joining A and Z into pieces A B, B C, C D, &c., Y Z. Then evidently

$$P_A - P_Z = (P_A - P_B) + (P_B - P_C) + \&c. + (P_X - P\ ) + (P_Y - P_Z),$$

or the difference in the values of P at A and Z = sum of the differences for all the pieces into which the whole path A Z is broken. $P_A - P_Z$ is, therefore, expressible as a line-integral along the path; if ds is an element thereof, the element of the integral is

$$P\, d s - \left(P + \frac{d P}{d s}\right) d s = - \frac{d P}{d s}\, d s$$

Consequently,

$$P_A - P_Z = \int_A^Z - \frac{d P}{d s}\, d s = \int_A^Z R \cos \epsilon \, d s \quad . \quad . \quad . \quad . \quad (III.)$$

This theorem is sufficiently obvious. It is added for the sake of completeness. If P be the electrostatic potential, R is the electric force, and its component $= - \frac{d P}{d s}$ in any direction s. If P be the magnetic potential of electric currents R is the magnetic force, provided that the line of integration does not pass through electric current. For the magnetic force has no curl where there is no current. Magnetic force is, therefore, derivable from a scalar potential-like electric force everywhere except where there is current. But it must be added in this case that $P_A - P_Z$ is only the same for the two paths, provided they do not embrace a current, for if they do, the line-integral of magnetic force once round the closed curve formed by the two paths will equal the surface-integral of the curl of the magnetic force over any surface bounded by the curve, and this surface will have current through it at some places, and there the curl is not zero, but $4\pi \times$ current density.

A comparison of the three theorems is instructive. Starting with the third theorem, we find that the difference in the values of a *scalar* function at the two points = line-integral of a derived *vector* along any connecting line.

Join the points by a second line, thus forming a closed curve, and the second theorem tells us that the line-integral of a *vector* once round it = surface-integral of a related *vector* over any surface bounded by it.

Lastly, let two surfaces have the same bounding curve, so that, taken together, they form a closed surface; the first theorem tells us that the surface-integral of a *vector* over it = volume-integral of a related *scalar* throughout the enclosed space.

Here we stop. Space has but three dimensions, and we cannot make a fourth to please anybody. Starting with a scalar for points, we have vectors for lines and surfaces, and a scalar again for a volume. I am not able to fathom the nature of the corresponding magnitude to be integrated in four dimensions, but probably it does not matter.

PRACTICAL LABORATORY CIRCUITS FOR SECONDARY BATTERY WORK.

In *The Electrician* for the 4th instant there are some notes by Mr. R. M. Bosanquet, in which he describes his difficulties in charging secondary batteries with the Gramme dynamo, difficulties which occur in some degree with all but shunt dynamos, or with those which obtain the current for the field magnets from an exciter.

Mr. Bosanquet's method of charging is to connect the terminals of the machine by a wire of about 5 ohms resistance, then to connect the batteries to be charged in arc with it, and finally to disconnect the wire. But, as he justly remarks, "there is a period of instability at the moment of removing the resistance, and the machine is often reversed before the high speed is established; the only means of obviating this are (1) to cram on every available pound of steam at the moment, (2) to execute the two operations of joining up the battery and removing the resistance in such quick succession that the speed has not time to fall. By the use of both these precautions I have generally succeeded in starting the charging in this form; but until I had acquired considerable experience and a thorough understanding of the conditions I frequently failed."

Now, by Mr. Bosanquet's own confession this plan is at best an uncertain one. There is another difficulty, by the way, which he omits to mention, viz.:—that, if for any reason the charging current is stopped, there is still more difficulty in beginning again than there was at first starting, owing to the batteries having acquired during the previous charging an electromotive force slightly higher than their normal one, probably due to the oxygen and hydrogen occluded at the anode and cathode respectively.

Diagram I. will explain the plan which we employ for charging with the Gramme.

When the movable arm of the 13-way switch S is turned, it touches the next contact piece before it leaves the one it is on at first, thus never breaking the main circuit.

To begin with, this arm is put to the first contact piece, and the current turned on by the main switch A (Diagram II.). If the current is shown by the detector F (consisting of a compass wound with a few turns of thick wire) to be in the wrong direction, A is turned off and the current reversed by means of the pole-changer H. A is then turned on again, and as soon as the ammeter G shows the proper charging current, say 20 amperes, S is slowly turned round, thus gradually bringing in the accumulators, five at a time for the first few, and then by twos and ones until the whole battery is in circuit. There is thus no need "to cram on every available pound of steam" (foot of gas in our case), and, therefore, no sudden strain on the engine, counter-shafting, &c.

There is another convenience in this arrangement, which is that in discharging, the last few cells can be added one by one, as is often required, especially when working incandescent lamps. Diagram II. shows our resistance table, which will be seen to be arranged as follows:—$\frac{1}{8}$, $\frac{1}{4}$, and $\frac{1}{2}$ ohm round the four-way switch B, one ohm between each two contact

Digitized by Google

pieces of the sliding switch C, which thus gives from 0 to 7 ohms, and an 8-ohm coil on the three-way switch D.

By this arrangement the resistance can be varied by ·125 ohm at a time, from $\frac{1}{8}$ ohm to $15\frac{7}{8}$ ohms. We employ spring coils one inch in diameter of German silver wire, No. 16 B.W.G., stretched between the table and the floor as shown. They are fastened by long staples, not driven home, so that the German silver never touches wood. Each ohm is joined to the next one, and to the copper wire from its contact piece on C, by a terminal or a Britannia joint.

The simplest method of coiling the wire, if a lathe is not available, is to make a hole in each end of a wooden box, and pass a piece of $\frac{3}{8}$in. rod through, with a handle at one end. (Diagram V.)

When the wire has been coiled close together, it is pulled out considerably beyond stretching point, then slipped over

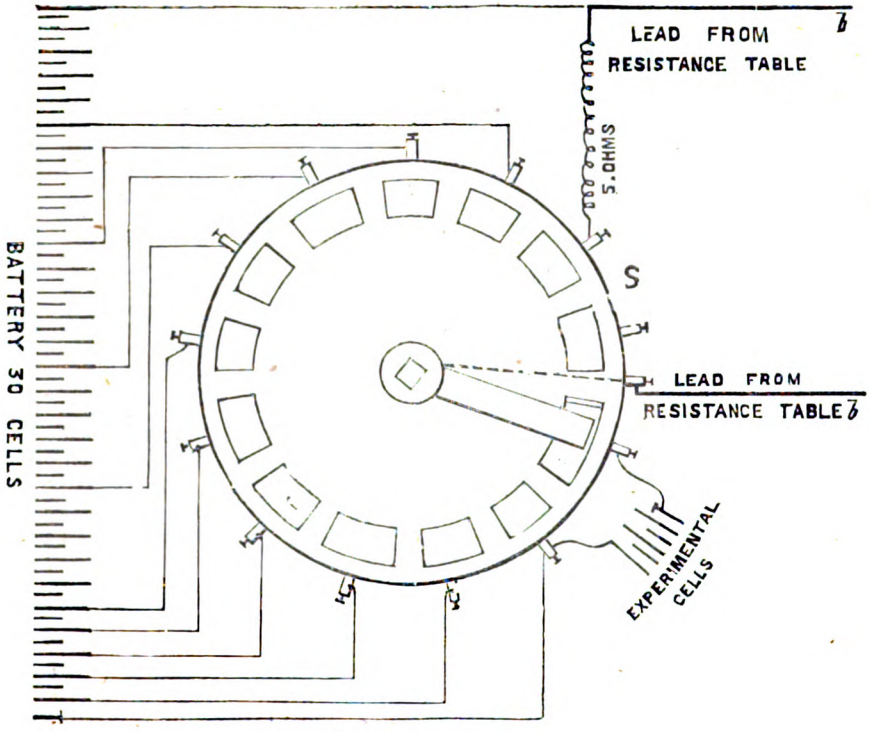


Diagram I.

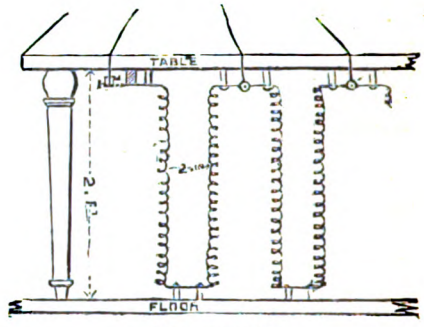

Diagram III.

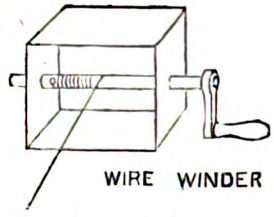

Diagram V.

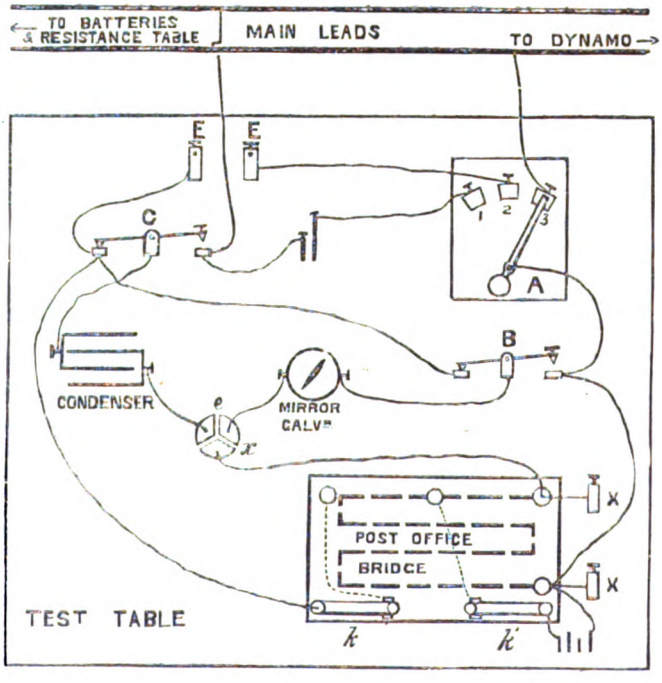

Diagram IV.

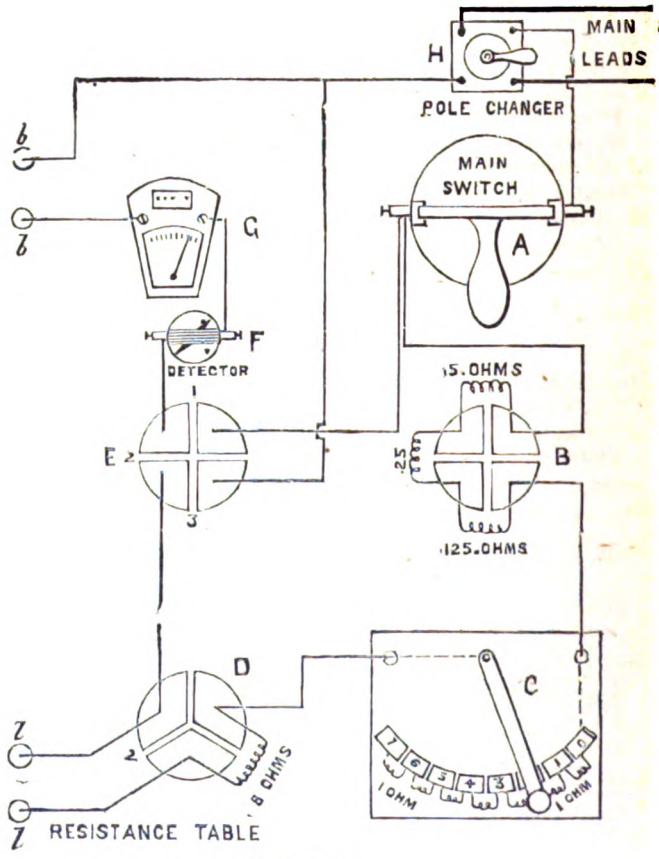

Diagram II.

Digitized by Google

the rod again, the coils pressed up together and the handle turned until all is tight again. This will give a perfectly even spring, with the coils about the right distance apart. The middle of each ohm must, of course, be straightened out to fasten to the floor.

Sixteen ohms on this plan only require an area of 22in. × 10in., allowing 2in. between each coil. The ventilation is so thorough that we pass a current of 25 to 30 amperes through No. 16 wire without injuring it, though Mr. Jehl's formula, given in his paper on "Electric Lighting at Brünn," gives 16 amperes for this size.*

As part of the resistance we have a circuit of 25 incandescent lamps, in multiple arc, round the laboratory and adjoining rooms, starting from the terminals *l l*, with a small switch on each lamp. Resistance hot of each lamp = 44 ohms, and current required = 1·2 to 1·3 ampere, so that when we require a resistance of $\frac{44}{25} = 1{\cdot}8$ ohm or more, and a current of $1{\cdot}3 \times 25 = 32$ amperes or less, the plug D_2 is pulled out, the number of lamps being adjusted to the current. Thus if, when charging the batteries with an 18 ampere current, we have to add a resistance in series of $5\frac{1}{4}$ ohms, we use $\frac{18}{1{\cdot}2} = 15$ lamps, $R = \frac{44}{15} = 3$ ohms, and make up the $5\frac{1}{4}$ ohms by using $2\frac{1}{4}$ ohms of wire resistance.

In order to work the lamps in this manner, we plug 2 on the four-way switch E.

Now it is often convenient to have the lamps alight when we have not sufficient E.M.F. to work them in series with the accumulators. By plugging E 1 and 3 we have the lamps together with the wire resistances in multiple arc with the batteries. In practice, we find it almost as easy to regulate the charging current with this arrangement as with the resistance in series with the batteries.

Diagram IV. shows the plan of our test table, which will be found a very simple and convenient one for taking E.M.F. of standard cell, dynamo, battery, and any experimental cell, the internal resistance of the latter two, and any ordinary resistance by means of the bridge. The method of working is as follows:—

Plug *e* for all but external resistance by the bridge.

Switch A to 1, and depress both B and C; this gives throw of the standard cell.

Switch A to 3 and depress both B and C; this gives throw of dynamo if charging, or of battery if dynamo be cut off.

Switch A to 2 and depress B only; this gives the throw on open circuit of any cell connected to terminals E E, and thence its E.M.F., by the well-known formula $E = \frac{a \times 1{\cdot}457}{D}$, where a = throw of cell to be tested and D = throw of standard cell.

The same formula is, of course, employed to obtain E.M.F. of dynamo or battery.

For finding the internal resistance of single cell unplug a resistance R in bridge; depress *k*, then B, obtaining deflection β, when by the usual formula internal resistance $= R\frac{a-\beta}{\beta}$ (a being throw as obtained above).

By introducing the key C we make it absolutely impossible to short circuit or put through the resistance box either the standard cell, the battery, or the dynamo, whatever keys may be accidentally depressed or plugs wrongly placed.

N.B. B and C must both be released before the condenser can be discharged.

It would be obviously impossible to circuit the whole battery through the bridge coils without injuring them, but we may measure its internal resistance with sufficient accuracy as follows:—

Disconnect the dynamo, and on the resistance table (Diagram II.) turn on the main switch A, arrange a suitable resistance on this table, plug E_1 and $_3$, and turn on the 13-way switch to include as many cells as we require the internal resistance of, which are thus circuited through the resistances, the deflection β being obtained before the coils have time to heat perceptibly.

The leads between the battery and the resistance table are so short and thick that their resistance may be ignored.

In employing the test-table for taking ordinary external resistance joined to the terminals X X, plug *x*, and work with the keys *k* and *k* on the bridge box in the usual manner.

C. W. S. Crawley,
School of Electrical Engineering, E. C. Rimington.
12, Princes-street, Hanover-square, W.

* By-the-bye, a more convenient expression for this formula for English electricians would be:—$16\sqrt{I}$ = diam. in mils.

TELEPHONE WIRES AND THE FIRE IN MANCHESTER.

TO THE EDITOR OF THE ELECTRICIAN.

Sir: My attention has been drawn to a paragraph on page 28 of your issue of the 25th inst., respecting a large fire in this city on the 17th.

As the portion of the paragraph has been copied in many other papers, and as its inaccuracy is calculated to do our company great damage, I must ask your permission to send you a reply, in the confident hope that you will insert it in your paper:—

You say—"The warehouse was in the centre of the business portion of Manchester, and, with the exception of the Royal Exchange, was the most important centre of overhead wires in the city. Fully 300 wires converged on the building, or passed over it, and were in the midst of the fire. A few of them broke soon after the fire had heated them, and fell into the street. The main portion held out until the roof of the warehouse fell in, and they were then broken by hundreds, and the ends of most of them fell in a state of white heat into the streets, or on to the roofs of the adjoining buildings. The whole of the telephonic and telegraphic communication with the most important portion of the city was absolutely destroyed. . . . . The hanging wires were a source of great danger for the time being." The *facts* of the case are these: The warehouse in question was not the most important centre save one in the city. Of the 800 exchange and 280 private wires we have in the City only 47 "converged on or passed over" the building in question. Of these five were attached to two chimneys and 42 were fixed to a standard.

Neither the chimneys nor the wires fixed to them gave way at all; the standard fell with the roof, but all the wires fell with the standard, and rested upon the wall eighty feet above the street. Not one of them broke; consequently there were none, either at a white or red heat, dropping into the street. They remained fixed to the head of the standard till the following day, when our own men cut them down with due precautions for the safety of the public.

The telegraphic communication was *not* destroyed, as there was not a telegraph wire on the building, and part of our communication was restored on the Monday morning following, and the whole of it on Wednesday morning.

Allow me to add—as it is now the fashion to wage a bitter war against overhead wires—that during the three years' existence of our company only one wire has broken in this city. This was last winter, when a chimney pot was blown off in a gale, and in its fall it cut one wire, which fell harmlessly and gently into the street.

How different the reality to the imaginary description!—Yours, &c., Joseph Thompson, Managing Director.

Lancashire and Cheshire Telephonic Exchange Co. (Lim.),
38, Faulkner-street, Manchester, Nov. 28, 1882.

DYNAMO FOR BICYCLE.

TO THE EDITOR OF THE ELECTRICIAN.

Sir: Will you kindly say if there are any dynamo machines made small enough that would fit on the head of a bicycle to light it in place of a lamp? Speed could easily be got to drive it a few hundred revolutions per minute.—Yours &c.,

Soho Foundry, Barrow, Nov. 25, 1882. P. Howell.

MILITARY TELEGRAPHS IN EGYPT.

In venturing to offer a few remarks on the paper read at the Society of Telegraph Engineers and of Electricians last week we feel, perhaps, like the chairman who presided on that occasion, in a would-like-to-know frame of mind. As civilians, we approach military subjects, even those closely related to telegraphy, with becoming modesty, and a due sense of our presumption in approaching them at all. Still, we would like to know one or two puzzling things about which we are unable ourselves to offer any explanation. And we want to know them, not in the spirit of fault finding, but in order to form a correct judgment upon the value of telegraphy in military movements, and the limits of possible usefulness at critical moments in actual battle.

It is no disparagement to say of Col. Webber's interesting account of the telegraph operations connected with the expeditionary forces in the late Egyptian war that it did not afford any explicit information on these points. That the telegraphs were extremely useful to the public we all know; that their maintenance was a task of considerable difficulty we can well believe; but that they were of great service to the army is a point still left in some uncertainty. Colonel Webber being a military man, and on active service in this campaign, laboured under two disadvantages in giving an account of his stewardship to a non military and irresponsible audience. As became a man of war he was silent, or at all events not communicative, on those very points which would have interested his hearers most, namely, personal narratives; and as a servant of the War Office he was reticent on just those matters of organisation and administration which would have been considered most instructive. This was unavoidable, and even commendable; but on that very account the lecture left a sense of something lacking, something which any "special correspondent," for example, with a quick eye and a ready pen, might have easily supplied. Nor was this all; there were some conspicuous gaps in the narrative, and one or two quite surprising episodes, which not unnaturally provoked the would-like-to-knows referred to above.

We would like to know, as did the chairman of the meeting, how it happened that the officer, who in our ignorance we fondly supposed was in sole charge of the military telegraphs, arrived at the enemy's deserted telegraph office alone. An ideal operation would have been so planned that a party of military telegraph constructors and manipulators should follow close on the heels of the advancing British lines, ready, so to speak, to join the Kantara wires to those communicating with Cairo; possibly, also—by prearrangement—with Alexandria. Somebody at least, one might have supposed, would be in readiness to work the circuits as if nothing had happened, to send delusive messages, if such a course seemed expedient, or at any rate to read whatever signals appeared on the wires. We do not presume to say that it would have been better if this had been done, and we are ready to admit, on proof shown, that things turned out just as well as they were. What we mean is that the ideal arrangement was not carried out, and we are still wondering why it was not. What really happened was that one officer of the Royal Engineers' Telegraph Corps found himself in possession of an important line of communication—in the telegraphic sense of the word—unable himself to work it, and with nobody belonging to him within reach. That there was no want of foresight is evident from the officer himself making straight for his mark. No lack of presence of mind either, for a couple of Highlanders were promptly laid hold of to put the leading wires in order. "Highlanders!" inwardly exclaimed the audience, "where were Colonel Webber's own men—those highly-trained and incomparably smart men who can turn their hands to anything in the matter of telegraphy, from digging holes and staying poles to keying messages and adjusting relays?" Blue jackets and Highlanders are admirable men; Colonel Webber had to make use of the former on many occasions, and of the latter on a critical one; but they are not the military telegraphers on whose training and equipment so much pains have been bestowed. Fortune favours the brave; and at the Tel-el-Kebir telegraph station—if we understand the account correctly—she came in the shape of a couple of battle-stained warriors in plaids, and a somebody else belonging to the Intelligence Department, who providentially could work a Morse instrument, and had scented it out in the fray. That the corps, a portion of it at least, which might have followed its adventurous chief, was not unemployed on that eventful morning we are quite sure. We know that some of them were with the telegraph waggons on either flank of the attacking force, for one of the men has

Digitized by Google

been decorated on account of services so rendered in the action. But as to the rest, they may, for all we know, have been impressed into the fighting lines, leaving the telegraphs to their fate. And this conjecture seems the more probable when we learn that the Royal Engineers in this campaign were in reality commanded by an officer who was not a telegraph engineer at all.

We have no military opinion to offer on the fact just mentioned; but, from a telegraphic point of view, it does seem as if somebody in high authority set very little value on the employment of electricity in the operations of warfare. There is no doubt something to be said on the other side. For the moment the success of an attack is of first importance, and every additional man contributes to the certainty of success. Perhaps, also, nobody suffered by the temporary withdrawal of the men—if they were withdrawn, for we speak on surmise—except those incurably frivolous persons who, it seems, are as common in the army as elsewhere, and who therefore regard telegrams as indispensable even on a field of battle. Something was said about this class of people, and the inconvenience they occasioned by rendering censorship a most arduous duty to prevent a complete blockage of traffic. To a commanding officer for whom the statistics of telegrams forwarded and received during a campaign have no interest whatever, this luxury of the telegraph, we can quite believe, may appear a not unmixed boon. A certain rough-spoken general once shouted to a kilted regiment among the furze bushes, "If you don't kneel properly I'll put you in breeks, and be blank to you!" In some such spirit a non-telegraphic engineer may treat all sumptuous provisions for sending telegrams to friends at home from the battle field. One can fancy him saying, If you want to send a message send it yourself—*if you can*.

And this reminds us of one other little bit of information which casually came to light in Colonel Webber's discourse. We refer to the importance of officers as well as men being able to work the telegraph when they have got it. Every administrator of telegraphy knows the value of this accomplishment, whether he possesses it himself or not; to every military officer of field telegraphs its acquisition ought to be an imperative duty. Of this we are perfectly sure, although we are only civilians who say it. We confidently appeal to the experiences of this campaign in Egypt in proof of our assertion. Cases must often arise—did arise, we believe—when some ticklish operation with which an officer of rank ought alone to be trusted has to be performed by a subordinate, as well as cases where an officer gets isolated, and is, consequently, useless if he can neither work nor read the instruments skilfully. We venture to commend this frank expression of opinion with all respect to those whom it may concern.

It was exceedingly gratifying to hear that the expedition went out with a telegraph equipment perfect and complete beyond anything ever attempted before. But, on the whole, we are inclined to think that a civilian or semi-military corps of telegraphers, not liable to be called to do duty as soldiers except in self-defence, would be a useful adjunct to any future expedition. Mr. Patey, the secretary of the post office telegraphs, informed the meeting that he had had numerous offers from volunteers, and there would, therefore, be no lack of men if their services should ever be desired. Be that as it may, the experience gained by an accomplished and energetic officer like Colonel Webber cannot fail to be turned to good account between now and the next campaign.

STUDENTS' COLUMNS.

CITY AND GUILDS EXAMINATIONS.

[*These answers are intended to guide, to give information and references, to put the student in the way of getting information, and* NOT *to give the exact answers that should be written in an examination.*]

The solutions in this number are contributed by E. C. Rimington, Esq. (School of Electrical Engineering), 12, Princes-street, Regent-street.

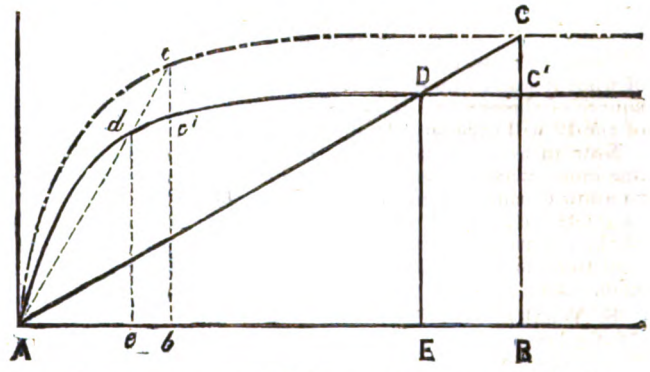
6. What is the E.M.F. in volts of a Daniell and of a Grove cell? What is the E.M.F. of the dynamo you are best acquainted with, running at some definite speed, and with some special resistance in circuit? How, exactly, is this E.M.F. altered by increasing the speed? In the case of a magneto machine, how does the E.M.F. vary with the speed? Explain fully the cause of the difference, if any, in the effect of speed on E.M.F. in the dynamo and in the magnetic machine.

Ans. The E.M.F. of a Grove cell = 1·97 volts.
" " Daniell " = 1·079 "

The next two parts of this question would hardly be of interest to our readers.

With regard to a magneto-machine, the E.M.F. varies in direct proportion to the speed, provided the exciting current remains constant.

In a dynamo, on increasing the speed, the E.M.F. will increase in a greater ratio, provided the resistance in the circuit be kept constant, as long as the current generated is not sufficient to saturate the field magnets. When, however, this is the case the E.M.F. becomes approximately proportional to the speed. This may be shown in the diagram.



Here A *d* D represents the characteristic curve of the dynamo for the lower speed, and A *c* C that for the higher, A *e* and A *b* represent the current, and *b c* and *e d* the E.M.F. in both cases. The resistance in each case is represented by tan *c* A *b*, here *b c* > *e d*.

Now, when we come to the flat portions of the curves, which represent the field magnets at their points of saturation, A B represents the current for the higher speed, and A E for the lower, the E.M.F.'s are represented by the lines C B and D E, but in this case E D = B C.

In a magneto machine, when the exciting current is kept constant, the magnetic force of the field magnets is also constant and entirely independent of the speed.

9. Describe in detail the construction of the incandescent lamp you are best acquainted with, and explain how the various types of incandescent lamps differ from one another.

Ans. We may divide incandescent lamps into two classes, viz.: those composed of natural fibres, and those composed of fibres chemically treated in order to render them more dense.

Of the former, the Edison, consisting of carbonised bamboo, the Maxim of carbonised cardboard, and the Lane-Fox, in which the fibre is made from carbonised "Monkey Bass," such as is used in carpet brooms. Of the latter, the Swan, in which a fibre of crochet cotton gelatinised in a dilute solution of sulphuric acid, and then carbonised is employed, and the FitzGerald, where paper is treated with a solution of zinc chloride, then compressed, and finally carbonised, is employed as a fibre.

10. A Grove battery of 20 cells will light from one to twenty ordinary lamps in parallel circuit, but the *fewer* the lamps the *more* the light given out by each. On the other

Digitized by Google

hand a Gramme machine will not light one ordinary incandescent at all, but will light twenty or thirty well. Explain fully what this difference depends on.

Ans. This difference arises partially from the fact that the Grove cells have to be joined up in series in order to obtain sufficient E.M.F. at the terminals of the lamps, consequently the internal resistance amounts to something considerable. When one lamp is being lit the current through it is (*e.g.*) one ampere, when we add another in parallel circuit with the first the total current is rather less than two amperes, giving not quite one ampere through each lamp. Now, when we add 20, the total current is considerably less than 20 amperes, thus we do not obtain a current of nearly one ampere through each lamp.

Let C = the current when we have one lamp in circuit.
„ C_1 = total current when we have n lamps in circuit.
„ c = current through each lamp when we have n lamps in circuit.
„ R = resistance of each lamp.
„ ρ = internal resistance of the battery.
„ E = actual E.M.F.
„ n = number of lamps in parallel circuit.

Then
$$C = \frac{E}{\rho + R},$$
$$C_1 = \frac{E}{\rho + \frac{R}{n}},$$
$$c = \frac{I_1}{n} = \frac{E}{\frac{\rho + \frac{R}{n}}{n}} = \frac{E}{n\rho + R}.$$

Let us suppose R = 30, and $\rho = 2$, $n = 17$.
When we have one lamp in circuit,
$$C = \frac{E}{32};$$
when we have 17 lamps,
$$c = \frac{E}{34 + 30} = \frac{E}{64}.$$

Thus the current through each of the 17 lamps is only one-half of what it was through the one lamp, and as light varies as the square of the current, if the one lamp gives 16 candle-power each of the 17 will give only 4 candle-power.

Now, in working the lamps from a dynamo, the resistance of one lamp, which is not likely to be less than 40 ohms, is too high to allow of sufficient current being produced to excite the field magnets; if, however, we add 19 more, we reduce the resistance of the external circuit to two ohms, thus allowing a strong current to be produced amply sufficient to saturate the field magnets. This, of course, does not apply to a shunt dynamo.

8. What are the essentials of a good electric lamp? How does a lamp for reverse currents differ from one for direct currents? What also is the difference between the carbons employed in the two cases?

Ans. The essentials of a good electric arc lamp are that the carbons should be maintained at a distance from each other, which gives the best arc as the current varies. The lamp must also be provided with a convenient arrangement for bringing together the carbons when the circuit is broken, and allowing them to separate to the proper distance for forming an arc when the current recommences. A good lamp should give as steady a light as possible, and not consume much more current than is necessary to produce the light. In a lamp for reverse currents the carbons are both consumed equally, while in one for direct currents the positive carbon is consumed about twice as fast as the negative. Lamps for alternating currents are generally arranged on the differential principle, in which the main coil and the shunt coil are arranged one above the other, the effect of one on the armature core being thus partially counteracted by the other.

MOTORS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Can you or any of your readers tell me where I can get a few electric motors specially designed to drive shafting and very light machinery?

I want from five to six horse-power at 1,200 to 1,500 revolutions per minute, and I would like something more portable than the ordinary reversible dynamo.

If you will kindly help me I shall be grateful.—Yours, &c.,
W. H. MASSEY.

Twyford, Berks., 27th November, 1882.

A GUIDE TO PRACTICE IN THE SUBMARINE CABLE TESTING ROOM.

IX.

We have thought it better to defer the consideration of the working out of particular tests till we have gone over the practical execution of those which we may call "regular," as distinguished from special operations, proposing to discuss that part of the subject in a number by itself. For this reason we have not fully worked out a "capacity" test, which will, however, be treated of in its place.

We are now about to treat of the subject of measuring insulation as applying to a cable, having already touched upon it in Numbers IV. and V. when showing how this quality is observed by means of the quadrant electrometer. The operation is called a test for insulation resistance; this is in some respects a misnomer, and one uninformed on the subject might imagine it meant the quality of resisting insulation, whereas it means just the reverse. When testing the insulation resistance, we measure the degree in which the insulation resists that which tends to reduce or oppose it. An analogy exists between conductive resistance and insulation resistance with reference to a cable. The former is a feature of the copper conductor and the latter of the insulating envelope, but we do not regard both of them in the same light. As a quality, the one is not on all fours with the other. Conductive resistance in this respect is not a desirable feature, whereas insulation resistance in its true meaning is to be commended. In measuring the first the less there is of it, generally speaking, the better, but the latter is all the more desirable the higher or greater it is. We look for small resistance in the conductor, but the contrary in the insulating cover. It must also be remarked that the proportion

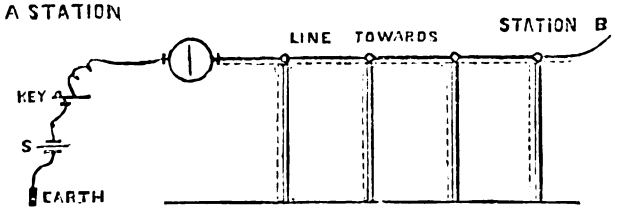


FIG. 18.—Leakage on a Land Line. Current passing.

between the resistance of a length of cable and that of any part of it is on exactly opposite conditions in the two cases. In a length of ten miles, for example, the copper resistance of the whole is ten times that of each mile, supposing it to be perfectly similar throughout; but the insulation resistance of the whole ten miles under the same limitation is only 1-10th that of each mile. The reason of this appears at once if we alter the expression in the latter feature, and say, "the resistance to insulation, or the *leakage*" is ten times greater for ten miles than for one or each mile. Every mile of the conductor has its 1-10th of resistance, and the whole ten has ten times the quantity. So with the leakage—every mile adds to the amount, and the result is the same. But the opposition to leakage, or the resistance called insulation resistance, is less for every added mile. Of course there would be ten times as much resistance to leakage in each mile as there is for the whole ten; for there are ten portions, each of which weakens or lessens the resistance. We are not concerned with land lines in these papers, at least at this point, or we might show that the conditions governing their qualities are the same as for submarine cables, that is to say, leaving out of the question the insulating supports. A glance at Fig. 18 will bring the matter out clearly. The dotted lines show the leakage.

The insulation resistance can be measured either by the galvanometer or the electrometer and by various tests in both instances. We shall show how to take the test with both instruments, giving at first one method for each. At a later stage we shall have to consider other modes of testing, the more ordinary operations being appropriate at this point. The galvanometer test will first claim our attention, and we have already introduced the electrometer as a means of observing insulation. At the same time the learner is reminded that we have only shown how to observe but not how

Digitized by Google

to measure the quality. We must point out that all these so-called measurements are really only comparative; we merely compare one observation with another. For example, by observing what result a known quality or measurement gives under certain conditions we find what an unknown similar measure is by the results it gives under similar conditions. Take the capacity test as an instance. The known capacity of the condenser gives us a certain deflection; by comparing the deflection for the cable we find its capacity also.

After this manner the insulation resistance of the cable is measured. We start with the determination of a standard to which the cable is to be compared. The technical expression is "finding the constant." This word in its application to our immediate subject requires some explanation, which will precede the actual operation; we shall reach the point very shortly.

Now, it must be remarked here that in speaking of the insulation resistance of a cable, we are dealing with resistance of very great amount. To realise this truth we must have some idea of the meaning of the test; its theory demands a moment's thought. Authorities are not absolutely agreed on this point, the process is differently explained. But the simplest way of looking at it fortunately coincides with the opinion of the person best qualified to pronounce upon such matters, as we think, and the view is this: When we take an insulation test we are doing pretty much the same thing as when we take a copper resistance test. The difference lies in the fact that the resistance is comparatively small in the latter case, because the material we deal with is very different. Moreover, the resistance is constant in the latter case and increasing in the former. The units with which we measure are the same, but we have hundreds in the one case, and hundreds of millions in the

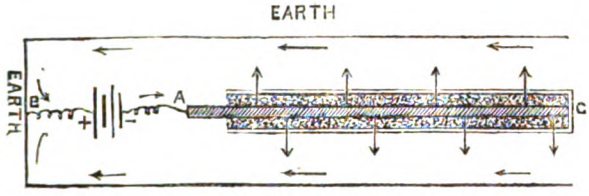

FIG. 19.—Cable Charged. Circuit through Insulating Cover.

other. The best way of regarding substances with relation to their conducting or insulating qualities is to say that a good insulator is a bad conductor of electricity. A good conductor presents small resistance, a good insulator presents very high resistance; and as in all cases of measuring electrical force a complete circuit is established reaching from one battery pole, through all the conducting path round to the other pole, an insulation test, so called, involves the existence of such a circuit, which we will therefore proceed to trace. See Fig. 19. Here the circuit is marked with arrows, and we trace it from the negative battery pole to A at one end of the cable whose other end is insulated. The cable is supposed to be under water, and as we are, for the sake of illustration, regarding the case as one in which a current is established, the conductor must have the means of connection with earth, as otherwise there would be nothing beyond an accumulated charge. The circuit then is continued from the copper conductor through the insulating cover to earth, and this at every point of the surface. We cannot represent this correctly, but must be content with allowing a few points to do duty for the whole, and mark the path with the arrows continuing the circuit to the other pole of the battery by way of the earth connection at B. The case is in this way analogous to an ordinary circuit through a copper wire to earth at one end, with one battery pole also to earth. We do not intend to say that this view completely explains the operation when insulation resistance is measured. It is sufficient to give an idea of what takes place, and by and by we shall consider the matter more closely.

The connections for the test will be exactly the same as those in Fig. 16 for the capacity test, but a large number of cells will be used, from 100 to 300, according to their nature and electromotive force. The cable will be connected up as before in either of the ways pointed out. It is sufficient for our purpose to suppose it joined at B in the galvanometer commutator (Fig. 16A). The ordinary insulation test is commonly taken with the negative current, the positive current being most generally used when reversal tests are taken, as we shall show further on. The reason for this is, briefly, that a negative current is regarded as more searching, and as giving a more faithful indication of the condition of the cable than the positive current. The latter tends to conceal or heal up any fault, and, therefore, the former has the preference, though no idea of anything wrong is suggested.

We shall first go through the operation by charging and observing the results which follow in order to give as clear a view as possible of the conditions, and afterwards take the test in regular form. We must premise, however, that in practice we could not safely do this with the cable, because it ought to be quite free of all electrical charge when testing its insulation, and if we once charge it with, say, 200 cells, it would be necessary to put it to earth for a long time, an hour or two or more, perhaps, to discharge it thoroughly. We shall, therefore, to avoid repetition, and at the same time to proceed with a necessary part of the operation, suppose the cable removed from B, and a high resistance put in its place. This resistance will be a million ohms, or a *megohm*, and is the standard to which we are to compare the results given afterwards by the cable. This is the value commonly used for the purpose, and by which we determine the "constant" mentioned above. It is defined as the "constant of the galvanometer with a given battery power." As the insulation resistance of the cable is very great we require an extremely high standard for comparison, and by the device now under notice we obtain a value amounting to many thousand millions of ohms. The constant, literally speaking, is "that number of ohms, or rather of megohms (millions of ohms) which it would be necessary to have in circuit with our* galvanometer and battery in order to cause a deflection of one division to appear on the scale." Of course, we have no such resistance in any form of coil or otherwise, but by using a megohm and introducing a shunt into the circuit we can get such a deflection on the scale as would, when multiplied by the multiplying power of that shunt, amount to the required value. This will appear from observing the operation of taking a constant; meanwhile, any apparent difficulty in grasping the truth is much lessened by remembering that the quantity of electricity passing in a given time through a conductor is *inversely* proportional to the resistance of the circuit; in other words, the strength of the current decreases as the resistance increases, and as the deflections on the scale represent the strength of the current, the smaller the resistance is the larger will be the deflection in any one instance. The "constant" is called the co-efficient for one division, and its value in ohms is found by passing a current through a megohm with necessary shunt, thus getting a certain deflection; then, by multiplying that deflection by the multiplying power of its shunt, we have the resistance of the constant in megohms or millions of ohms. For example, if the deflection were 300 and the multiplying power were 150, the constant would be 45,000 millions of ohms. This amount (45,000) represents the number of divisions the deflection would have given without a shunt when there was a resistance of one million in circuit. From this it clearly appears that if 45,000 millions had been in circuit the deflection would have been one only. The meaning of the operation is that, with the particular battery power

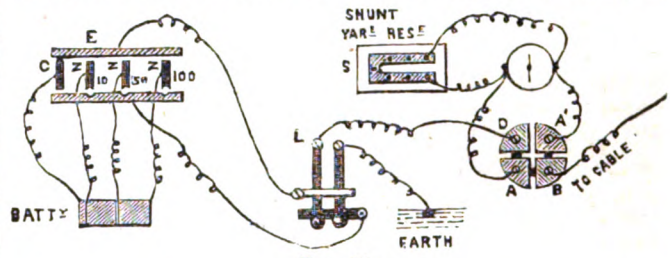

FIG. 16A.

* By this is meant "that particular galvanometer and battery power."

Digitized by Google

employed, the current through a resistance of one million ohms causes the galvanometer we are using to give a deflection of 45,000 divisions when the whole of the current passes through it. We purposely leave the resistance of battery and galvanometer out of this calculation as relatively so small.

The learner may be somewhat puzzled at first to understand the real proportion between the divisions (of the scale) and the resistance. We may say that one division represents a million, since 45,000 divisions gives us 45,000 millions for our constant, but by keeping in mind the inverse ratio there will be no confusion. The best way is to consider the divisions as running from one upwards, and the resistances in millions as running from 45,000 downwards. Suppose the constant were only 10 millions, then one division would represent 10 millions, and by placing the figures in two rows we shall see the ratio. Thus:—

$$\begin{matrix} 1 & 2 & 3 & 4 & 5 & 6 & 7 & 8 & 9 & 10. \\ 10 & 9 & 8 & 7 & 6 & 5 & 4 & 3 & 2 & 1. \end{matrix}$$

In the case of our constant of 45,000 millions, each division upwards on the scale represents a million less resistance, till at the 45,000th we have the one million which gave us the deflection $300 \times 150 = 45{,}000$.

Many operators can take an insulation test, and, therefore, know how to get a constant, but many of them do not know, or do not stop to think what it really is. Its usefulness consists in giving us a standard to which to compare the cable. If we know what amount of resistance one division represents in a given instance, we can easily determine that of the cable by observing what deflection results from keeping a current passing through its insulating cover.

THE ELEMENTARY PRINCIPLES OF ELECTRICITY.

II.

The fact that amber and some other bodies, when rubbed, acquire the power of attracting light objects was known to the ancients, and was mentioned by Thales, of Miletus, about B.C. 600. It was also referred to by Theophrastus and Pliny. The latter philosopher also mentions the shocks given by the electric torpedo. During the middle ages some few isolated observations were made, which can only be explained by the excitation of electricity by friction, but these observations do not appear to have led to any experimental inquiry. Dr. Gilbert, of Colchester, physician to Queen Elizabeth, may properly be regarded as the founder of the modern science of electricity. Gilbert found that a great many substances, a full list of which he enumerated, were capable when rubbed of attracting a light metal needle, which was balanced on a point, but that the readiness with which this attraction could be exhibited depended on the hygrometric state of the air. Other substances refused to exert any such attraction. To Gilbert we owe the word *electricity*, and he called those bodies in which the power of attracting light bodies could be excited by friction "*electrics*." Bodies in which this power could not be so excited he called "*non-electrics*." This distinction we shall presently find is without a scientific basis. The first electric machine was constructed by Otto von Guericke, who also discovered electric induction. Newton was the first to employ a glass globe, with which electricity was produced by friction against the hand, and Hawksbee employed a similar generator. In 1729 Stephen Gray discovered electric conduction, and subsequently succeeded in conveying electricity to a distance of several hundred feet by means of thread supported by silk strings. Desaguliers pointed out that the reason why some bodies could not be electrified by friction was due to this conducting power, which caused the electricity to escape as fast as it was generated. Early in last century Dufay showed that all bodies could be electrified if supported on an insulator or non-conductor. He also discovered the dual character of electrification, showing that the electrification generally excited upon glass by means of friction, which he called vitreous electricity, is opposite in character to that excited upon sealing wax, and that bodies similarly electrified repel one another, while bodies electrified in opposite ways attract each other. As the electric machines employed by Newton and Hawksbee furnished vitreous electricity much more readily than resinous electricity, it came to pass that when the terms positive and negative were applied to the opposite kinds of electricity, that furnished by glass was called positive and the other negative.

The substitution of a blown cylinder for Newton's sphere, of a leather cushion covered with silk—over which a metallic amalgam was spread by the help of a little grease—for the hand, and the addition of the prime conductor and the silk flap, which by its negative electrification serves to diminish the tendency of the positive electrification of the glass to run back to the rubber, completed the cylinder electric machine, which is too familiar an object to require a detailed description. By the friction of the glass and the amalgamated rubber the glass becomes positively electrified, while the negative electrification of the rubber is allowed to escape to earth as the positively electrified glass recedes from it. As the cylinder is turned the electrified rubber attracts the oppositely electrified glass, resisting its motion, and work has to be done by the operator against the electrical attraction, the work so done corresponding to the electrical energy of the machine. Besides this the positive electricity on the glass tends to creep along its surface back to the rubber, and if the attraction become very strong, it will fly back in sparks before it gets far away from the rubber. The silk flap, however, becoming negatively electrified exerts a counter attraction, and thus induces the electricity to remain on the glass until it has got so far from the rubber that it is unable to return. It then reaches the end of the silk flap, and is shortly afterwards presented in front of the prime conductor.

The action of the prime conductor affords an example not only of electric induction but also of the behaviour of points. When the positively electrified glass comes opposite to the points of the prime conductor it attracts negative electricity from the conductor, which, rushing off from the sharp points, neutralises the positive electricity of the glass, but leaves the conductor itself charged with positive electricity. The sparks taken from the conductor of this machine serve to ignite gun cotton, alcohol, &c.

Two theories have been proposed to account for the behaviour of electrified bodies. The two-fluid theory was first clearly stated by Symmer; the one-fluid theory was first proposed by Sir Wm. Watson, subsequently developed by Franklin, but more completely by Œpinus and Henry Cavendish. According to the two-fluid theory there exists in every body a combination of two electric fluids, which are exactly opposite in their qualities, so that, by combining in equal quantities, they completely destroy one another's effects, and no test with which we are acquainted serves to detect the presence of the so-called neutral fluid. In this respect they resemble positive and negative quantities in algebra, which, when numerically equal, produce zero by addition. For the reason mentioned above vitreous electricity is regarded as positive, and resinous electricity as negative. Every unelectrified body is supposed to contain equal but unlimited amounts of each of these fluids, which, however, resemble fluids only in their power of *flowing*, and are not to be endowed with mass or any of the other properties of ordinary fluids. Like kinds of electricity repel and unlike kinds attract one another with forces proportional to the product of the charges, and inversely proportional to the square of the distance between them, the dimensions of the charged bodies being supposed very small compared with their distance from each other. A body may be positively charged by giving it positive electricity, or by subtracting from it negative electricity, or by both these operations.

According to the one-fluid theory of electricity, as developed by Œpinus and Cavendish, every body in its normal condition consists of a combination of matter with a definite proportion of electric fluid. For want of any reason to the contrary the electric fluid is identified with positive or vitreous electricity. A body which contains more than its normal charge of electricity is said to be positively electrified; one which contains less than its normal

Digitized by Google

charge is negatively electrified. Hence that which is regarded as pure matter in this theory is matter negatively charged to the highest degree of which it is capable. We have no experience of matter in this condition. The theory also supposes that the electric fluid repels itself, but attracts matter, while matter, of course, attracts the electric fluid in return, but repels itself. The hypothesis that matter repels itself was necessary to explain the repulsion existing between negatively electrified bodies. This was considered by some to contradict Newton's law of gravitation; but it must be borne in mind that the law of gravitation has been proved true for matter as it exists in nature, that is, combined with its normal proportion of electric fluid, and not for matter negatively electrified to the highest degree of which it is susceptible. Between two bodies, A and B, according to the one-fluid theory, there exist four stresses, viz., repulsion between the electricity of A and that of B, repulsion between the matter of A and that of B, attraction between the electricity of A and the matter of B, and attraction between the matter of A and the electricity of B. In the case of bodies which possess only their normal charge of electricity, the repulsions very nearly balance the attractions, but we may suppose that the attractions are very slightly in excess, the difference corresponding to the attraction of gravitation.

The law of electrical action, viz., that the attraction or repulson between two charges of electricity is directly proportional to the product of the charges, and inversely proportional to the square of the distance between them, was first shown to be approximately true by Coulomb's torsion balance. In this apparatus a small ball was attached to the end of a shellac rod, which was suspended by a fibre from a torsion head, and was repelled by means of a fixed ball charged with electricity, the balls having first been brought in contact so as to distribute the charge between them. The repulsion at different distances was measured by the twist which had to be communicated to the fibre in order to maintain the balls at each particular distance from each other.

But Cavendish proved "the law of inverse squares" experimentally by a method which admits of far greater accuracy than the employment of the torsion balance of Coulomb. Cavendish showed that no electricity exists on a conductor placed inside a closed conducting sphere, and in metallic communication with the sphere, however highly the sphere may be charged. Now, it can be shown that if the law were other than that of the inverse square of the distance this could not be the case. If, for example, the force varied inversely as the distance, or according to any inverse power lower than the inverse square, the interior of a positively electrified conducting sphere would be electrified negatively, while if the law were that of the inverse cube, or any inverse power higher than the inverse square, positive electricity would be distributed throughout the interior of a positively electrified sphere. As it is possible, by modern electrometers, to detect the *millionth* part of the charge which may conveniently be given to a conductor which is inside a hollow sphere, and which may be put into communication with the sphere, or insulated at will, this method of Cavendish affords a most delicate test of "the law of inverse squares." An experiment of a similar character was performed by Faraday on a very large scale. Faraday built a cube of nine feet edge, and having insulated it he placed lighted candles, electrometers, &c., within. He then remained inside the cube while it was charged by an electric machine until long sparks passed from its edges, but no trace of electrification could be detected by any of the instruments within the cube.

Having thus experimentally proved the truth of the law of inverse squares, we may base upon this law a system of absolute units for the measurement of electrostatic quantities.

Def. The unit of electricity is that quantity of positive electricity which, acting *through air* upon an equal quantity at a distance of one centimetre, repels it with a force of one dyne.

This unit may be roughly realised experimentally by taking two lead shots, each weighing one gramme, and suspending them from the same point by two very fine fibres, each 490·5 centimetres in length. Now, if we suppose the acceleration produced by gravity to be equal to 981 centimetre-second units, the weight of a gramme will be equal to 981 dynes, and the force required to deflect a gramme when suspended by a thread 490·5 centimetres long, through a horizontal distance of ·5 centimetre, will be sensibly equal to one dyne. Hence, if the shots be electrified till each hangs ·5 cm. out of the vertical line through their common point of suspension, and the shots are, therefore, one centimetre apart, the horizontal repulsion between them will be equal to one dyne. The charges of electricity upon the shots will then each be equal to the unit of electricity as defined above.

In defining the unit of electricity it is important to state that the action is supposed to take place *through air*. If the repulsion take place through other non-conducting media (or *dielectrics*, as they are called when considered with reference to the transmission of electric stress through them) such as glass, sulphur, resin, shellac, paraffin, liquid, hydrocarbons, &c., the quantity of electricity required to exert a force of one dyne on an equal quantity at a distance of one centimetre is much greater than when air is the medium through which the stress is transmitted. This is due to what is called the *specific inductive capacity* of the dielectric.

STORAGE BATTERIES.

TO THE EDITOR OF THE ELECTRICIAN.

Sir: Permit me to tender my sincere thanks and congratulations that you have so timely commenced a series of papers for beginners in this week's issue. It is just what I have been looking for. I am pleased at the way you have commenced, and with what you promise us in the future. May I ask you to be as explicit and full as you can find time and space for, and may you lead us from the rudiments on into the higher branches of the subject. I should feel much obliged if you will kindly answer the following:—

I have a friend who has fitted up two small installations of incandescent lamps, and in both cases circumstances are such as to render the use of storage batteries especially needful and welcome. But my friend tells me there are none to be obtained. Although advertised, &c., he says the company will not sell batteries to any one, they merely doing a money-market exchange business. He applied for a ton, but could not get them for love or money. Now, here is the point I wish for information upon. I am constantly reading in your paper of storage batteries being used, and this week I see Crompton and Co. are fitting up some lamps on ship board, and are going to supply batteries for the same. Will you kindly tell me how these people obtain batteries. Is it possible to get them by any means?—Yours &c.,

106, Western-road, Brighton, Nov. 27. F. Cowley.

OHM'S LAW.

TO THE EDITOR OF THE ELECTRICIAN.

Sir: I am but a tyro in electrical science, and Ohm's law, as laid down by most text writers, puzzles me.

$$C = \frac{E}{R}.$$

That means, as I understand it, that current or available force equals the electromotive force divided by the resistance. Now, assuming that E is 12 and R 2, it follows that C = 6, and if E is 12 and R 4, C = 3, in the one case a reduction of 6 where the resistance is 2, and a reduction of 9 when the resistance is 4. Now, why 2 should make a reduction of 6, and 4 only make a reduction of 9 is what I cannot exactly comprehend. I have my own notion of what the real fact is, but as that involves a contradiction of what is so universally admitted as truth, I should be very conceited if I did not think I am under some mistake. Perhaps some of your skilled readers will kindly enlighten me.—Yours, &c.,

Nov. 24, 1882. J. A. S.

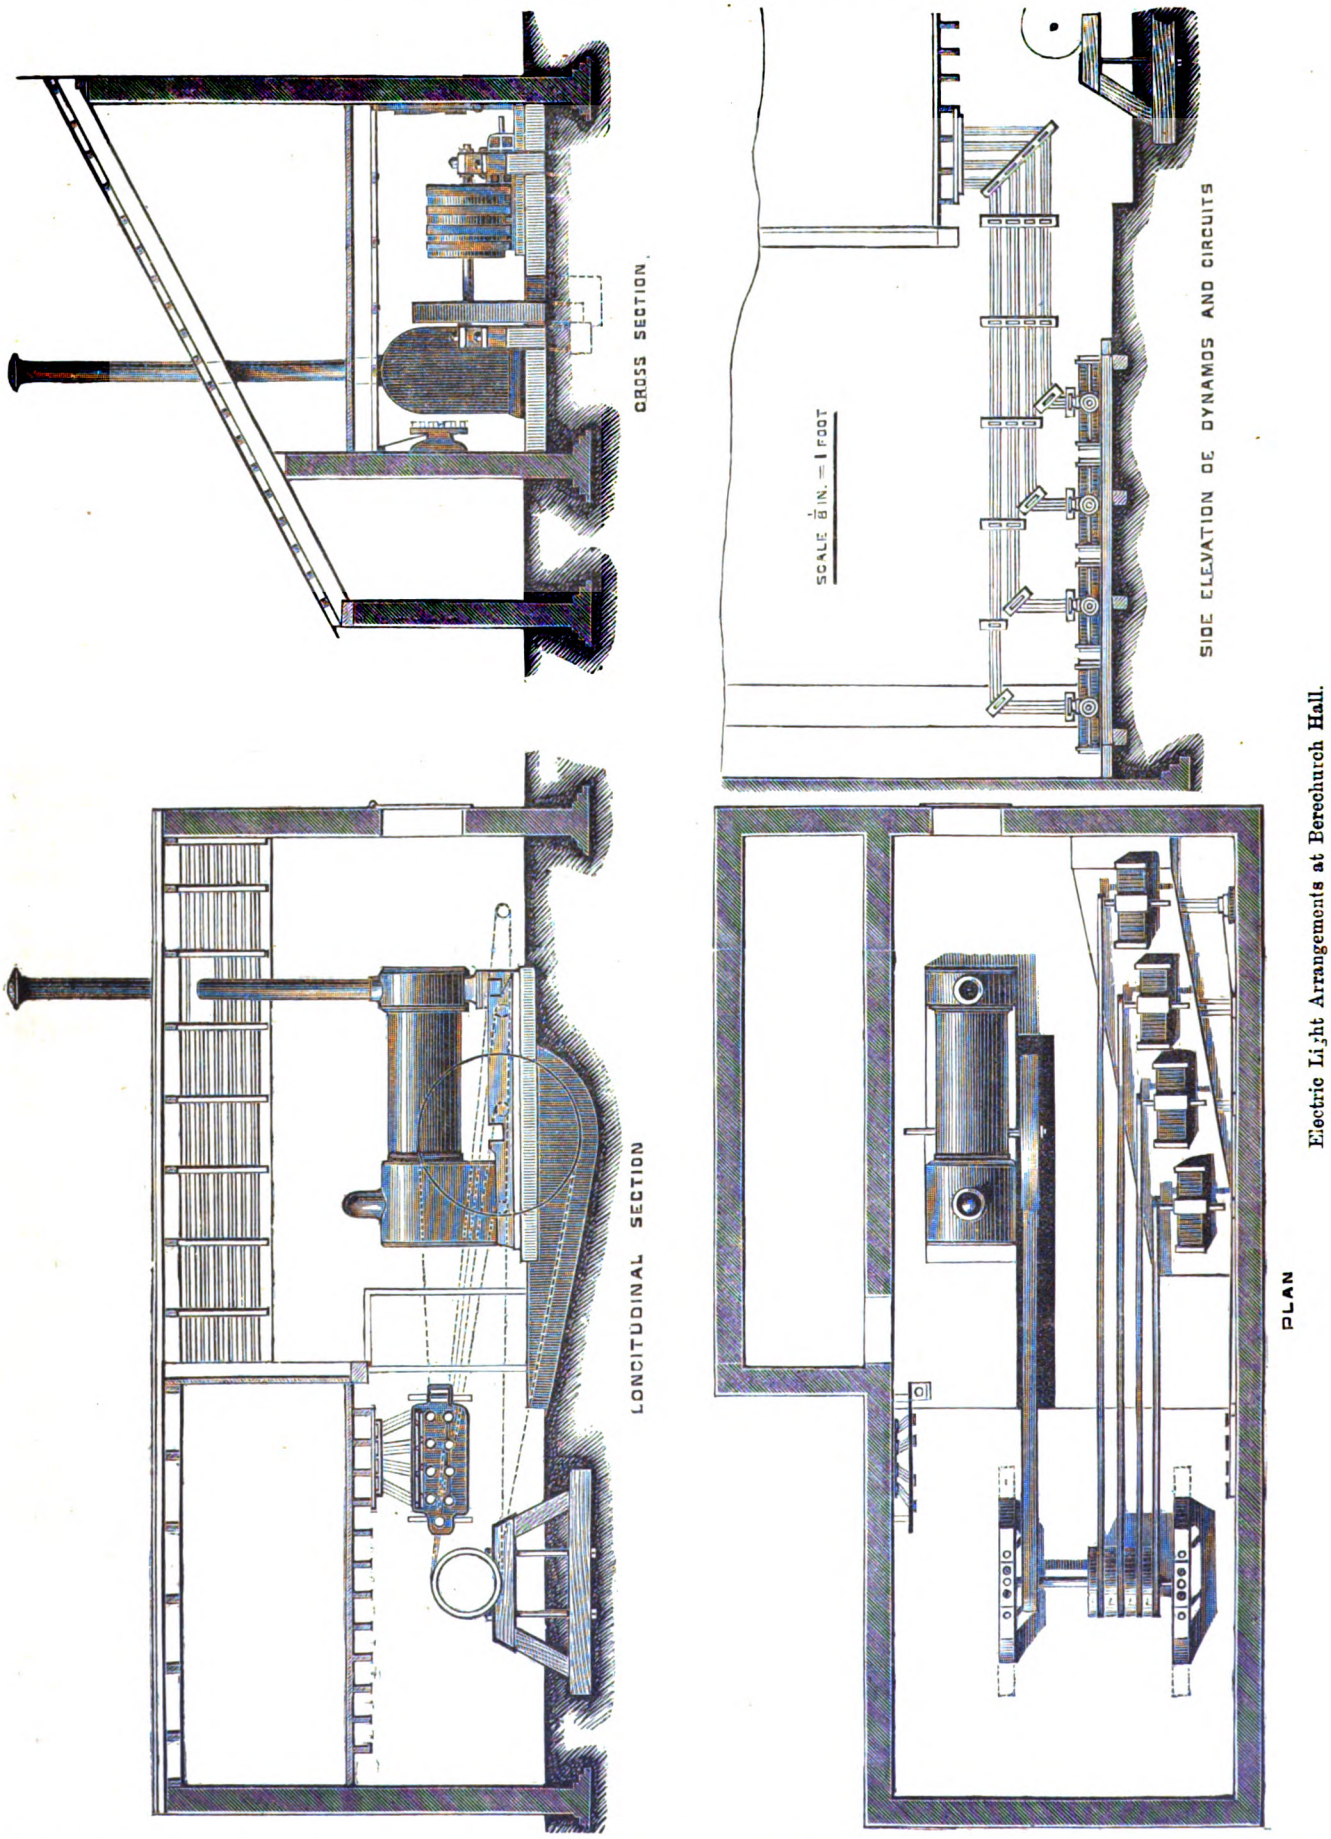
THE ELECTRIC LIGHT AT BERECHURCH HALL.



Electric Light Arrangements at Berechurch Hall.

When Mrs. Hemans wrote about "The Stately Homes of England" she had in view those old ancestral mansions which dot the landscape throughout the whole of rural England. However these mansions may lend themselves to poetic

Digitized by Google

fancies, the realities of life necessitate the erection of other and newer residences. Age may give its charms, but science also plays its part, and lends itself to the increase of artistic beauty, lends itself, too, to the minimising of much that is detrimental to health and pleasure. The electric light has many advantages to commend it over candles, oil, or gas, and these must sooner or later cause its introduction into the mansions of the wealthy. One of the most, if not the most, complete installations in existence has just been made by Messrs. R. E. Crompton and Co., at Berechurch Hall, near Colchester. With the exception of two rooms, the Hall has been completely rebuilt by O. E. Coope, Esq., M.P., the foundations of the ancient building being chiefly followed. The two apartments retained are the large reception rooms in the east wing, the walls of which, however, have been refaced, and the windows remodelled. The new building is faced with red bricks and stone, and is of late 15th Century style, with mullioned windows, gables, dormers, tall chimneys, and square turrets. There is a plenitude of carving, of a refined and delicate character, and full of quaint conceits. The bay window of the drawing room is said to be the largest in Essex. The door at the main entrance reminds one of olden times. It is solidly constructed in oak, and studded with iron nails. There is an old-fashioned ingle-nooked fireplace in the entrance hall, which is 40ft. square. Altogether, the house is a lordly one, and every subsidiary arrangement is worthy of it. There are hydrants, for instance, at each end of the building, on every floor, for use in case of fire, and there is a lift for coals, luggage, and other heavy movables.

It was originally intended to light the hall by means of gas, to be manufactured on the premises, and during the building most of the gas pipes were laid throughout the house. Later on, and we think justly, it was decided to put aside gas for the electric light. The only illumination used, then, is obtained from electricity, and therefore the arrangements are of an eminently practical and permanent character. The work has, as we have said, been carried out by Messrs. R. E. Crompton and Co. The lamps used are Swan lamps. The current is obtained from a new design of Crompton-Bürgin machine, driven by a Davey-Paxman engine. In all there are 200 (59 volt) Swan lamps fitted up at Berechurch Hall, of which number 170 are in the house itself and 30 in outlying buildings, such as engine room and stables, servants' house, &c. Of the 170 lamps 28 are in the basement, 74 in the rooms on the ground floor, viz., the large hall, dining room, conservatory, billiard room, &c., and 68 lamps in the first and second floors, consisting mostly of bed rooms. The lamps are all placed in single parallel circuit and provided with switches, so that each single light (or, where there is a group of lights, each group) can be switched on or off at will.

As a general rule the switches are placed above 4ft. from the ground in the surface of the wall, close to the door. Lead cut-outs are provided, first, to each branch circuit, feeding one single lamp or group of lamps; secondly, to each circuit feeding one floor; and, thirdly, to each dynamo.

The size of the lead is, of course, proportional to the number of lamps in each instance.

All leads are embedded in the wall, and lead cut-out boxes and switch boxes are let into the wall flush with it.

The electric light fittings have been supplied by Messrs. R. W. Winfield and Co., of Birmingham; all wires are taken down to the lamps inside the fittings, so that nowhere can a wire be seen.

The current is brought to the house and returns from it by a pair of heavily insulated cables, 19 strand No. 12, laid underground in earthenware drain pipes, which are, of course, kept dry. The cables are taken by the well of the lift, and at each floor the branch circuit supplying that floor contains a heavy current switch and lead cut-out, so that each floor can be cut out from the main circuit—a convenient arrangement for testing.

The current is supplied by four Crompton-Bürgin compound dynamo machines, all driven off the same countershaft, and each capable of delivering a current of from 1 to 65 amperes at a constant electromotive force of 60 volts in the circuit. As all four dynamos are coupled parallel, a special arrangement of connections is necessary to prevent reversal of current and short-circuiting of one machine through the other.

It will suffice to describe one machine and its connections on the switch board. The lead from the positive brush is brought to a terminal on the switch board, which is connected to one side of a switch, the other side of which is connected to a terminal by means of a short piece of stout lead wire. From this second terminal the current is taken back to the machine and enters the coils of the field magnets. After passing through these it is taken along another lead to a third terminal on the switch board, from whence it is brought by a short copper wire to one contact plate of a two-way switch, the two opposite contact plates of which are connected, each to one of the two horizontal gun metal bars, seen in our illustration on the top of the switch board.

Electrical continuity is maintained between these bars through a dynamometer inserted into a line joining their right-hand ends, and the current is taken off at the left-hand end of the top bar. It will be seen that by putting the switch on to either one or the other of the top contact pieces, the current is made to either enter directly into the top bar, or first through the dynamometer and then into the top bar. In this way it is possible to measure the current given off by each machine separately, or the current of several machines together.

The current after leaving the top bar passes through a reversing switch into the main cable, which conveys it to the house. The return cable is coupled to the other terminal of the reversing switch, and the current is led from thence to the bottom bar on the switch board. This bar is coupled to a terminal, from which a lead goes direct to the negative brush. This arrangement is repeated for every dynamo, with the exception, however, of the three bars, dynamometer, and reversing switch, which are common to all. There is another bar on the switch board, viz., that connecting the centres of all the lower switches.

It will be seen that, by thus putting all the terminals of the field magnet coils into electrical connection, all machines must necessarily have similar fields, and a reversal of current in any one machine is impossible.

The shunt coils are coupled up in the usual way from brush to brush.

The reversing switch is used only occasionally, as it has been found to increase the life of incandescence lamps if the direction of current is occasionally changed.

It will be seen from our engraving that there are eight pulleys on the countershaft. Four of these are fast on it and in line with the pulleys on the dynamos, and four are loose pulleys. To stop any of the four machines it is merely necessary to open its switches on the board, and to shift the belt on to the loose pulley.

The belt now stands slightly at an angle, but as there is no movement (the loose pulley standing still) it will keep so. If it be desired to put that machine into motion, it suffices to close its switches, when the current, flowing back through the bobbin, makes it revolve, and, in doing so, shifts the belt on to the fast pulley. This is a very neat experiment, showing the transmission of power by the electric current.

The power is supplied, as we have said, by one of Messrs. Davey-Paxman's 12 h.-p. semi-portable engines, with engine under boiler, making 125 revolutions per minute. The corresponding speed of the dynamos is 1,500 revolutions. The dynamo machines are self-regulating, that is to say, they supply within the limits for which they are designed a current always proportional to the number of layers which happen to be switched on at the time. In other words, they keep the difference of potential throughout the circuit constant. That the machines are entirely self-regulating can best be seen from the fact that, if two are working and a third is suddenly switched in, no appreciable change in the lights occur. The engine room is lighted by five Swan lamps.

Throughout the house it has been as much as possible avoided to mass many lamps close together upon one electrolier, and a system of more divided arrangement has been

Digitized by Google

adopted. Thus in the great hall, where it was originally intended to put three handsome pendants with seven gas lights each, nine single electric light pendants have been substituted. In no place are more than three lights grouped into one of the fittings, except the electrolier over the billiard table, where six lamps are used.

This system of distributing the lamps as much as possible is not only advisable on account of economising current, but also because the artistic effect is thereby much increased.

We propose to give further illustration of this installation next week, with an enlarged view of the switch board arrangements.

THE FERRANTI MACHINE.

The Ferranti machine has already obtained some notoriety, but it could not be said to be before the public till last Monday, when a large company was invited to witness its work. Before we describe the machine we may say that we can give no opinion as to its electrical efficiency. The facts from which to judge are not before us, and unless the facts are correct the conclusions will probably be wrong. In order to give an answer to the question whether a greater candle-power per horse-power can be obtained by using this machine than by using another machine requires not only a knowledge of the horse-power indicated by the engine, and the number of lamps running, but requires also that the lamps should be photometrically measured. It is easy to say a lamp gives x candles, it is difficult to prove without apparatus that it is at its normal candle-giving capacity. Eighteen candles instead of twenty in a hundred lamps means a diminution of two hundred candles. We merely state these things to show that any opinion expressed regarding this or any other machine, without experimental data, are not worth the paper they are written upon when employed to compare one machine with another.

The following paragraphs are taken from a pamphlet circulated on Monday evening:—

"The machine exhibited this evening is that producing an alternating current, and it is the joint invention of Sir William Thomson and Messrs. S. Ziani de Ferranti and Alfred Thompson.

"The attention of the makers is at the present moment being exclusively given to the production of this latter type of machine, in view of its suitability for running incandescent lights, and in consequence of the immense want existing at the present moment of a low tension machine, capable of running satisfactorily a large number of incandescent lamps.

"The machine, it will be noticed, is running 300 twenty candle-power "Swan" lamps, and careful tests show that this is being obtained by an expenditure of less than twenty-six horse-power, which includes the power absorbed by the small exciter."

We understood in the room that the machine was running 320 or 321 lamps, and not 300, as stated above. Of course, 320 would be a better result than 300.

Let us see the number of Swan lamps that could be obtained per horse-power, supposing all the power to be transmuted into electricity and given out in the lamp—an ideal state which many wish to obtain, but one hardly likely to be realised.

The A_1 Swan lamp gives 18 candles with an E.M.F. of 41 volts and a current of 1·46 ampere.

Thus the A_1 lamp absorbs

$$\frac{C \cdot E}{746} \text{ h.-p.} = \frac{1 \cdot 46 \times 41}{746} = \frac{59 \cdot 86}{746} = 12 \cdot 4.$$

It is impossible, if these figures are correct, to get 13 lamps per horse-power, and 12 lamps per horse-power is approaching perfection.

The B_1 Swan lamp gives 20 candles with an E.M.F. of 46 volts and a current of 1·32 ampere.

Thus the B_1 lamp absorbs

$$\frac{C \cdot E}{746} \text{ h.-p.} = \frac{1 \cdot 32 \times 46}{746} = \frac{60 \cdot 72}{746} = 12 \cdot 4 \text{ nearly,}$$

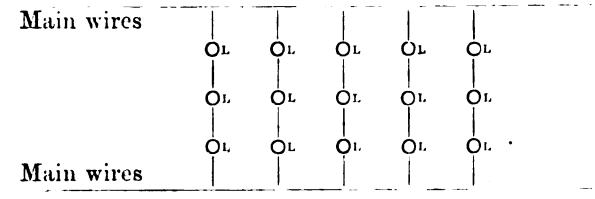
again showing—if the figures are correct—that only 12 lamps can be obtained under perfect conditions per horse-power.

We cannot, therefore, but think that some little error has been made in the claims above mentioned. We have not gone through the figures for the B, C, D, E, F, G, H, and I Swan lamps, which all are supposed to give 20 candles under certain conditions, but we should imagine that the maximum number of lamps per horse-power is about 12, and, therefore, candles per horse-power is about 240.

The figures given upon the wall at the experiments of Monday last were—

320 lamps,
160 amperes,
125 volts E.M.F.

The lamps were three in series, and each set of three in multiple arc, thus,



Taking 107 branches, that is $\frac{321}{3} = 107$, we get that the current through each branch, supposing resistances throughout exactly similar, $= \frac{160}{107} = 1 \cdot 49$ ampere, quite sufficient to keep the 41 volt lamps at their normal candle-power, but too much for the 46 volt lamps. Then, again, we should infer that 18 candle lamps were used, because the E.M.F. required for each branch is about $3 \times 41 = 123$ volts, whereas for the 20 candle lamp it is about $3 \times 46 = 138$ volts, in the former case the E.M.F. being about that of the machine as given, in the latter case somewhat higher. The difference between 18 and 20 candle-lamps taking 12 per horse-power is only 24 candles; but this is considerable when we are verging upon the confines of perfection.

Mathematicians have been so frequently laughed at by practical men that we are sorely tempted to cast aside our formula; but, perhaps, it will be better to wait a little, and to see if the startling results of 12 lamps of 20 candle-power are obtained in all ordinary installations. We are prepared to accept any facts, and believe nothing so probable as the unforeseen.

Turning now from the unknown to the known, we may say that this machine is one of the simplest we have ever seen. Those who noticed the machines of the White House Mills Company at the Crystal Palace last winter, and at the Paris Exhibition in the preceding autumn, will have some idea of a disc armature. It is essentially in its armature that the Ferranti machine differs from other alternate current machines. The field magnets are the usual electro-magnets, requiring an exciter. A small vertical Siemens was used at the exhibition on Monday. The armature, however, is the main point, and this we are particularly requested not to describe at present, because publication might interfere with foreign patents. There are, however, a few facts we may refer to which we venture to think will in no way invalidate any patent. It is well known that the armature is of copper strip, the total length of which in the machine exhibited is 120ft., the width 12·5mm., and the diameter 2mm.; weighing 18lb. 2oz. The resistance of the armature is stated as ·0265 ohm. It must necessarily be very low. The number of revolutions when running on Monday was 1,900 per minute, giving an E.M.F. of 125 volts. The general arrangement of the machine will be seen from

Digitized by Google

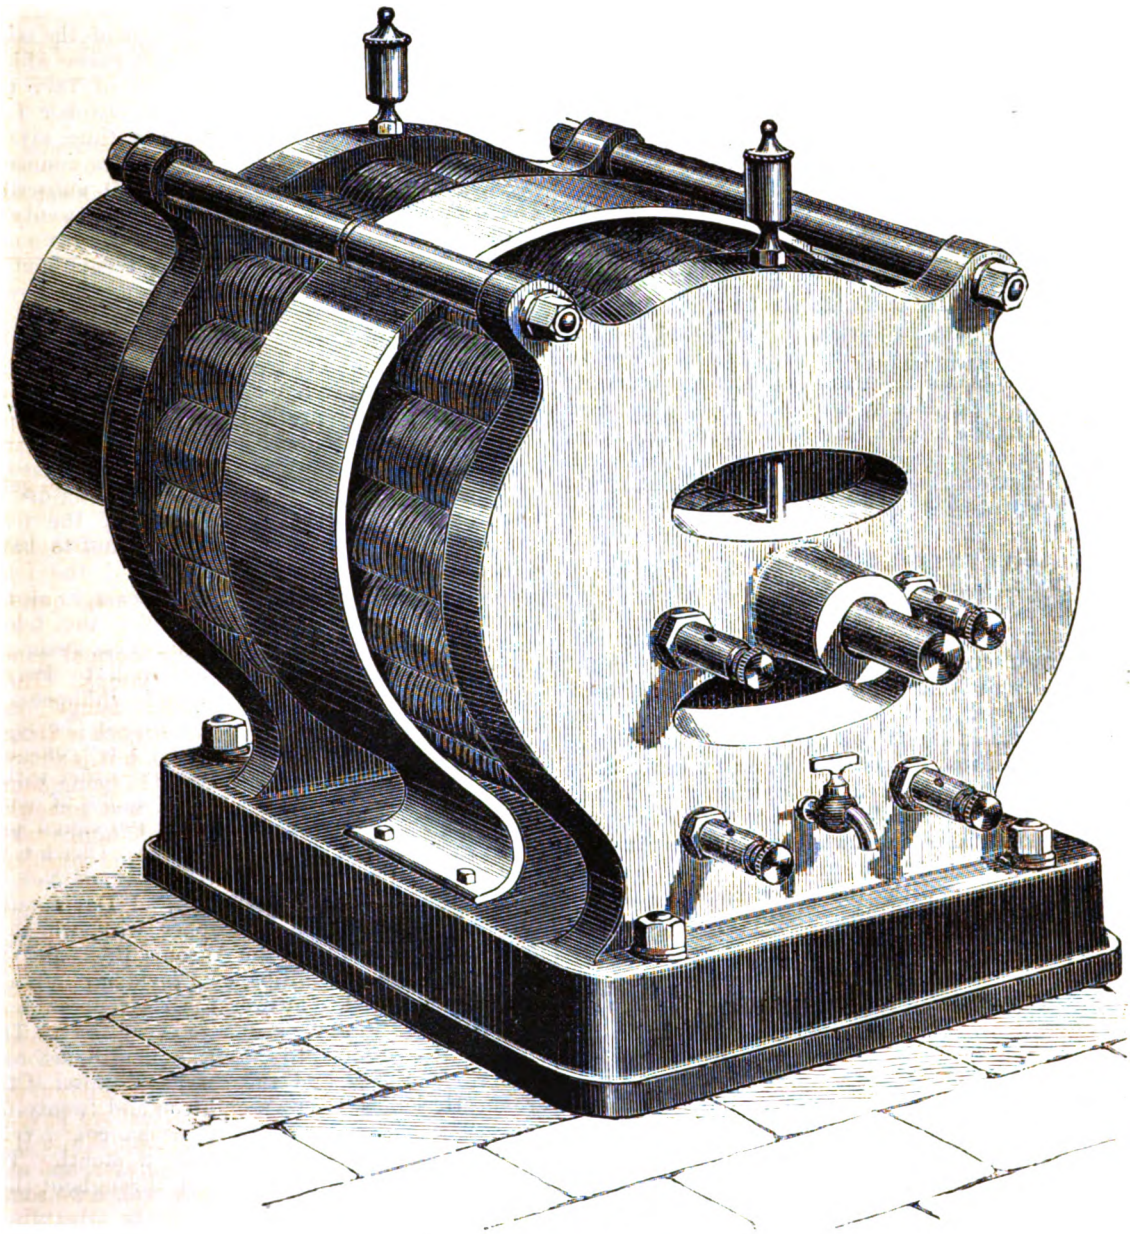
the illustration. The disc armature is hidden from sight by a brass ring. The field magnets are 32 in number, 16 on each side of the disc. Each core is surrounded by four coils of wire 3·5mm. diameter, and the coils are connected in series, the resistance being 2·5 ohms. The poles of the field magnets are arranged as in the Siemens alternate current machines. The current through the field magnet coils was 21·5 amperes, the exciter being, as we have already said, a small vertical Siemens machine, requiring about 1·7 h.-p.

The weight of the Ferranti machine compares very favourably with any other machine which we know, the one running weighing only about 11·75 cwt. The indicated horse-power of the engine when the machine was running the 300 or 320 lamps was under 27 h.-p.

We have already pointed out the difficulty in arriving at really valuable conclusions without having the whole of the required data. We may in the future have to modify our opinions regarding this machine considerably. Meanwhile we may say that, putting aside the exact electrical efficiency, it must necessarily attract considerable favour, because of its simplicity and small weight. The machine shown has, of course, the usual disadvantages of an alternate current machine. It cannot be used to transmit power, nor to charge secondary batteries, nor for electro-chemical work, and when the leads are very long and the branches numerous, the reversal of current a large number of turns per minute will have its effect, and, we imagine, will not increase the efficiency.

Since the first part of this description was in type we have learned that Mr. Swan has slightly improved his 18 and 20 candle-power lamp, so that 240 candles per horse-power could be obtained, providing the total power was converted into light in the lamp.

We hope to be able to illustrate the armature shortly.



The Ferranti Dynamo.

Western and Brazilian Telegraph Company.—The traffic receipts of this company for the week ending 24th November, 1882, were £2,713, after deducting the "fifth" of the gross receipts payable to the London Platino-Brazilian Telegraph Company (Limited).

LITERATURE.

HYDROSTATICS.

Hydrostatics, or Theoretical Mechanics. Part II. By J. T. Bottomley, M.A., F.R.S.E. [William Collins, Sons, and Co.]

A few years ago Messrs. Collins, having in view the requirements of the Science Examinations at South Kensington, and seeing that at that time trustworthy books on science subjects were few, undertook the publication of two series of scientific books. The one series was intended for the use of students for the elementary stages of the Science Examinations, the other for the use of advanced students. Mr. Bottomley has written two books for the elementary series, of which the one before us is the second. It may be thought that "Hydrostatics" has little to do with electricity, but the contrary is the case. The analogies between the phenomena of perfect fluids and electricity are many, and most teachers of electricity appeal more or less to these analogies to assist them in explaining electrical phenomena. Further, there are many electricians who believe elecericity to be an entity, a something approximating to a perfect fluid. Hence, a knowledge of the laws appertaining to fluids is of great importance to electrical students. As an elementary book the student will find this generally accurate, concise, and clear. We would have a few alterations. Among others we may mention one or two trifling ones. South Kensington science students as a rule do not read Greek, and although they may guess Hiero's exclamation, and title of his work, p. 41, they will not recognise εὕρηκα. Why not put eureka in brackets, 'tis almost an English word, and so for the title. Again, if we have no international scientific agreements as to a central position to be taken by *all* authors for figures in text books about barometric pressure, attraction of gravitation, &c., surely London to an Englisman has claims over Glasgow, Edinburgh, or Paris. Is every author to give the figures for the town he lives in? If so, our elementary text books will soon give rise to anathemas. Our opinion upon this subject is very strong, and we would not introduce as a class book to our students any book that took as the central point any other than the recognised capital of the empire. We live in hopes that authors will see the necessity of an understanding of this kind, and that any difference of opinion may be put aside in order to benefit the whole student world. The writer of this notice is not afraid to acknowledge himself a student, though at the same time a teacher, and having had a somewhat lengthy experience with the examinations at the southern universities, he may be somewhat prejudiced in this matter.

ELECTRIC LIGHT ARITHMETIC.

Electric Light Arithmetic. By R. E. Day, M.A. [Macmillan and Co.]

This very useful little book contains a series of questions involving the ordinary electrical formulæ, many of the questions having solutions worked out, whilst others are left for the student to solve. It is well understood by those who have a knowledge of the requirements of electric lighting that the vast majority of practical questions involve little more mathematics than arithmetic and simple equations. Mr. Day commences with questions on resistance, then on current, then heating effect, work, and so on. We are not quite sure whether we agree with the haste to use the nomenclature suggested at Paris and Southampton. We are quite sure that we prefer other symbols than those Mr. Day has chosen. It only requires Jones, Brown, and Robinson to write a few papers upon electrical subjects, and then to propose a new nomenclature altogether for another change. This matter is, however, outside of Mr. Day's book. The mere choice of I or C to represent current, the introduction of watts, amperes, coulombs, detracts nothing from the intrinsic value of a series of arithmetical and algebraical questions. For these we are thankful to Mr. Day, and only regret, for the sake of the student, that the work is not double the size. The young electrical engineer cannot work too many of these simple problems. He must gain valuable experience by patiently working out these questions, and the more so as the figures given by Mr. Day are figures derived from practice—by these we mean that the questions are absolutely similar to those which arise in the everyday work of an electrical engineer.

THE GROWTH OF TELEPHONE BUSINESS IN AMERICA.

An illustration of the rapid growth of the telephone business generally is found in the increase which has taken place in Lowell, Mass. In the fall of 1877 the exchange was started with sixty subscribers. October 1, 1880, it had 600 subscribers, and at the present time, says the *Boston Globe*, there are about 900 subscribers connected with the exchange, showing an increase of 150 subscribers a year. The company is now putting in about twenty new instruments a month in Lowell alone, and the ratio of increase to the population is about the same throughout the territory covered by the consolidated exchanges. Lowell has one telephone to every sixty-two of its population, a very large proportion. In Portland, Me., there are 700 telephones, and the ratio is one to every fifty of population, the largest ratio in the world in any city of the same size. Considering, however, that there are in Lowell 20,000 mill operatives, the large number of telephones in use in that city is even more remarkable. One would naturally suppose that the increased use of the telephone, particularly for long-distance talking, would seriously affect the business of the telegraph companies. Oddly enough this appears not to have been the case. In Lowell, for instance, to-day the telephone company receives and sends as many messages as the Western Union Telegraph Company, and yet the telegraph company is doing half as large a business again as it was two years ago. The distance from Lowell to Portland is 115 miles, and, unless the atmospheric influences are exceptionally unfavourable, conversation can be readily carried on between these two points. The consolidated New England companies have a standing order with Washburn and Moen, of Worcester, for 300 miles of wire a month. They also have standing orders for 400 signal bells a month from Post and Co., of Cincinnati, Charles Williams, of Boston, the Western Electric Company, of New York, Gilliland and Co., of Indianapolis, and Davis and Watts, of Baltimore. The insulated copper wire, which is used for inside work, comes from the Ansonia Brass and Copper Company and Eugene Phillips, of Providence. The number of operators required to answer the calls of subscribers is, in Lowell, fifteen to 900, or one to every sixty. The operators are paid from 18dols. to 30dols. a month, according to their ability, experience, and the service required of them. They are mostly ladies, between eighteen and twenty-four years of age. The superintendents of exchanges receive salaries varying from 50dols. to 100dols. a month. These are the average salaries paid for the work throughout the country.

Electricity and Plants.—Mr. A. J. Kunkel finds that leaf veins are generally positive toward the rest of the leaf, but the direction of the current is reversed if the spot on the leaf where the electrode is placed is wetted before the other electrode is placed on the vein. A spot long moistened is positive toward one freshly wetted. When a plant is bent or wounded, the electrode near the bend or wound is negative to the other. Dr. J. Burdon Sanderson has noticed somewhat similar phenomena in the leaf of the Venus's fly trap (*Dionœa muscipula*), the under surface of the sensitive lobe of the leaf being electro-negative to the upper at the moment that the leaf is irritated; after about half a second the upper surface becomes electro-negative, and remains so for some time.

THE SOCIETY OF TELEGRAPH ENGINEERS AND OF ELECTRICIANS.

On Thursday evening, the 23rd ult., the president of this society, Lt.-Colonel C. E. WEBBER, R.E., read a paper describing the operations of the telegraphs with the expeditionary forces in the late Egyptian war. The first part of the paper was occupied with a retrospective account of the rise and progress of military telegraphy in this country, associated with which in a most distinguished manner was the name of Colonel Frank Bolton, the hon. secretary of the society. So long ago as 1855-7 he had written on the subject, and had submitted plans to the Government, which were investigated by an ordnance and select committee, of which Field-Marshal Burgoyne was a member. In 1862 Colonel Bolton also read a paper at Chatham, where portable apparatus of his construction was exhibited, which in the following year was adopted in the army, and shortly afterwards by the navy. Colonel Malcolm's labours in the same direction were also gracefully acknowledged, his division of the signalling under four heads—namely, permanent, semi-permanent, field, and visual, being fully described. The number-code, which, together with other recommendations then put forward, were adopted in 1876, was advocated by Colonel Webber himself in 1872. Differing from other military authorities on the matter of organisation he had subsequently read a paper before the United Service Institute recommending central control for the army telegraphs under one administration, and Col. Webber was understood to say that his experience in the late campaign had confirmed the views then enunciated. Turning to the immediate subject of the evening, Colonel Webber then described the actual condition of the Egyptian telegraphs when the expeditionary force arrived. They are modelled on the Indian lines, which in most particulars they closely resemble, the poles, however, being similar to those seen in Austria. The insulators are of Mr. Andrew's pattern, and are fixed to opposite sides of the poles, the wires being carried diagonally, as is the case in France, where cross arms are not in use. The battery is the Minotti, and the rule for power is 12 cells per 100 miles in dry weather, 18 cells for wet. The telegraphists were partly Europeans of various nationalities, but mostly Egyptians, seventy per cent. of whom could signal in no language but their own. Many of the former had fled for safety, and most of the latter had, of course, joined the enemy. The first business of the expedition was to restore the lines—many of which had been damaged and deserted—to the Egyptian Government, as also the system belonging to the Eastern Telegraph Company, which, being European property, had been singled out with special malice for destruction. This applied especially to the line between Cairo and Suez, *viâ* Zagazig and Ismailia. The work of restoration was done under very trying circumstances, and was rendered possible only by the devoted and cheerful service of the blue jackets, who, anywhere and everywhere, turned their hands to whatever was found them to do in a manner which provoked the warmest admiration. The laying of the cable between Alexandria and Port Said, the maintenance of the line between the last-named place and Ismailia were next referred to. Later on, the line terminating at Zagazig was extended to Kantara, and a military wire also between Belbeis and Cairo was erected.

But as the crisis of the campaign approached, the chief anxiety was for the wires connecting the basis of operations at Ismailia with the front—that is to say, with Kasassin. Between Kasassin and Tel-el-Kebir it is needless to say the wires had been destroyed; and pending the final attack, the Kasassin and Ismailia circuit was the one on which fell the main brunt of the traffic. The work was most trying and arduous for the operators, the heat intense, the traffic heavy, and the flies insufferable. As the wires were carried along the railroad, and the railroad, besides being the track for trains, was also the chief highway, the poles had continually to be repaired, inspection at least twice a day being needful all the time. Sometimes the telegraphists' position was evidently one of considerable danger, though Colonel Webber did not speak of it as such. They were soldiers, and facing danger is, of course, part of their duty; but it probably struck the audience that it is one thing to face danger in the field, and quite another to be shelled in a tent while you have to keep "pegging away," not with a rifle, but with a Morse key. "As an illustration of how one may realise the actualities of warfare at a distance by means of the telegraph"—so Colonel Webber put it—"I may mention that one night the operator at the other end stopped the signalling, saying, 'I must change instruments as I cannot read by sound any longer for the firing.' There was a pause for about five minutes; then a call. "What now?" we asked, to which the answer came 'the firing is getting closer, I will go out and see what is happening.' We waited some few minutes, and then were told that a shell had burst close to the tent." This interesting little episode was pursued no further, but it seems that the telegraphing went on all the same, occupied with messages, which from a military point of view took priority even over shells.

When the attack on Arabi's position took place the first thing to be done was to ascertain how were the wires southwards to Cario. Col. Webber himself made straight for the railway station at Kebir, and there found the office in the utmost confusion, the Egyptians having fled from it only ten minutes previously. Mr. Clarke, of the Intelligence Department, called up one or two stations, and it was at once fouud that the lines had not been broken; and in due course they were joined through. During the fifteen days which followed, some 5,000 telegrams were signalled through the military offices alone, many of which, being cypher messages, required the utmost care in despatch. Col Webber believed that they had been signalled with great accuracy, a circumstance which he attributed to the capital training the men had had in England in the postal telegraph service.

Mr. W. H. PREECE, F.R.S., who occupied the chair, offered some appropriate comments upon the paper, in the course of which he inquired how it was that Colonel Webber arrived at the Tel-el-Kebir Railway telegraph office alone, and had to enlist the assistance of a couple of Highlanders, fresh from—or rather wearied with—the heat and toil of battle to get the wires in order? Where was the C troop of Royal Engineers? Was it the fact that they were commanded by an officer who was not a telegraph man at all?

To these questions Colonel WEBBER replied that, like the ways of Providence, the ways of the War Office sometimes were inscrutable, and he confessed he could not give Mr. Preece a quite satisfactory answer.

A hearty vote of thanks, proposed by Mr. ANSELL and seconded by Mr. PATEY, concluded the proceedings.

BRUSH ELECTRIC LIGHT AND POWER COMPANY OF SCOTLAND (LIMITED).

An extraordinary general meeting of this Company was held last Tuesday at the New Exchange-buildings, George-yard, Lombard-street, under the presidency of the Earl of Crawford and Balcarres.

The SECRETARY (Mr. Fred. M. Brockelbank) having read the notice convening the meeting,

The CHAIRMAN said: Gentlemen, you have met to-day in order to receive a statement from the Board as to certain proceedings which have taken place owing to a disclosure which was made in a letter by Sir Charles Bright, and to consider what would be the effect of certain actions which have been brought by some of the shareholders against the Company. Perhaps it would not be wrong if I were to say a few words to you first on the origin or history of this Company. In 1881, the Anglo-American Brush Corporation desired to push their business in Scotland, and therefore they entered into a certain contract with Mr. Hope to form a small company in Scotland to introduce their system, and later on they desired that he should form a larger company in order to work their patents on a more extended basis. Mr. Hope duly formed a company, which was called the Scottish Brush Electric Light and Power Company, and with his colleagues he then proceeded to lay the ground for the formation of this present Company, of which we are all members. Shortly before the formation of this present Company, two licenses were granted to the Scottish Brush Company from the Anglo-American Brush Corporation. Those licenses were dated the 14th of March, 1882, and I will, with your permission, refer to the items of those licenses more explicitly in a minute or two. Those licenses were handed over to the present Company on its incorporation, and they are referred to in its prospectus, and they are also scheduled in the contract. The prospectuses were issued, if I recollect right, on the 20th May, and the success in the applications for shares was a very remarkable one, I think I may say, inasmuch as though we had only 20,000 shares to allot, we had applications for 373,281 shares. The directors did all they could to work this allotment in as just and fair a manner as possible. I consider that the amount of labour which they spent on that object gave them very difficult work, and it was not a pleasant task, yet it was one which they did, and I think they did it conscientiously. The matters I wish now to draw your attention to are the questions of the licenses, those licenses which were handed over by the Anglo-American Brush Corporation on March 14 to the Scottish Brush Company. Having read the clauses relating to the granting of the Brush and the Lane-Fox licenses, he observed: Both these licenses, gentlemen, are in terms which may be considered exclusive licenses. I do not wish at the present moment to go into any question of argument as to the meaning of a word, but I can only say that the word was very carefully considered by the gentlemen who drew up the prospectus, in which they followed other companies. Other gentlemen had to draw up prospectuses, and they also believed the same thing—that by the license granted for the Lane-Fox patents we had the power of supplying Lane-Fox lamps for electric lighting, and that nobody else had that power of supplying the Lane-Fox lamps for electric lighting. Consequently this prospectus was issued by the gentlemen of the Board, who drew it up in all good faith, and they thereby believed that what they said was correct. Within a short time since, however, I am sorry to say a letter appeared, signed by Sir Charles Bright, and disclosing to us all that there had been a license granted to the British Electric Light Company previous to that which was granted to us. There is also with the license a covenant in a separate deed which was signed by the British Electric Light Company, agreeing that they would not in any manner use

Digitized by Google

the Lane-Fox lamp in connection with their license. Therefore, so far as I apprehend, the British Electric Light Company are in possession of a patent, but are not in possession of any means of selling the Lane-Fox lamp to the public, or of saying in any way whatever that their position has anything to do with the Lane-Fox lamp. They are merely able to use the method, but they cannot sell the Lane-Fox lamp in Scotland or anywhere else. Gentlemen, when I saw this letter of Sir Charles Bright I could not help asking myself a question—why was this not said before? Why has the Brush Electric Light Company permitted this false statement that it is said we have made to pass unnoticed for so many months? I have never tried to give an answer, and I decline to give an answer. Well, now, gentlemen, the next matter I have to bring before you is to inform you that certain shareholders of the Company have taken action against the Company, requesting a return of their capital—a return of the amount of money laid out by them in subscribing for their shares. Well, now, there are certain questions raised by the litigation which I may summarise shortly if you will permit me. First of all, the question will arise—Is the statement in the prospectus a mis-statement of fact. Shareholders will doubtless say "Yes," as the license is said in the prospectus to be exclusive, and it is shown that there is another license in existence. For the Company, we may say that the prospectus was not a mis-statement, for although the British Electric Light Company have, as I have already mentioned, the mere license for the patents, it cannot sell the Lane-Fox lamp under such a name. It can sell an article; it can sell a piece of glass in which the air is exhausted, in which there are filaments of carbon, and in which the carbon is in a certain shape. Well, gentlemen, all incandescent lamps are in that shape. They are all made of glass; all have a filament of carbon, I may say; the air is exhausted, and the electric current is passed through the wire; it gets white hot, and it emits light. Some call them the Lane-Fox, some the Swan, others the Edison, but there is very little difference between them. I said the British Electric Light Company have this license, but they cannot sell a Lane-Fox lamp. Assuming, however, that what we have placed before you is a mis-statement, the question will arise—Is it a material mis-statement—one which would entitle a shareholder to set aside his contract to take shares? To this—though, as a matter of fact, it is held that the Lane-Fox patents are no longer of any great value—I do not like to express my own opinion whether it could be said to be a material mis-statement or not. Of course it would be open for a shareholder to say before the judge that it was the Lane-Fox lamp that induced him to subscribe for shares in this Company. I do not wish, gentlemen, to state any theory of my own. I am a layman, I am not accustomed to the translation of the laws of this country, but still there is that probability that a shareholder might say "I held by the Lane-Fox lamp; it is the Lane-Fox lamp which caused me to subscribe for shares, and though the Lane-Fox lamp is now worth nothing, I will still try to get my money back." Well, now, in the event, gentlemen, of this litigation proceeding, there are certain effects possible, certain effects probable, and certain effects certain to the Company. We have to do with an unknown quantity when we go to litigation. We are in presence of the great infinite; we are unable to say how the carriage of justice will proceed. Very often it appears perfectly certain to both sides that they are in the right, and yet the judge is obliged to say that one is wrong, and I am afraid that very likely we shall come to that, unless gentlemen should see that it would be to their good that all these actions should cease. The actions may be successful, but it is not easy to foretell this matter. There is always this element of uncertainty. There is, however, one question which is absolutely certain, and that is that this litigation must involve the Company in serious expense in defending itself. It must also hinder us from carrying on the work of the Company, because it is impossible that we could carry on to any great extent with liabilities hanging over us which cannot be estimated for a considerable period of time. If we assume that these actions are upheld against the Company, in all probability we could not recover the blow, and we should then have to go into liquidation, and what I consider a really flourishing business would be thrown away. Even should the actions against the Company fail, still there is the expense of litigation, which I am sure everybody is glad to be out of. Then what I consider to be as harmful to the Company as loss of money by litigation is the loss of time, the loss of opportunity of pushing our system—for how can we go forward in Scotland, how can we take contracts over a series of years, how can we even go before other gentlemen with the view of purchasing what we consider to be of very great advantage to the Company—that is, an incandescent system—how could we propose to ourselves to lay out money while we are in this position? I think really that should the shareholders to-day, after having heard what has been said, give us some means of feeling that it is our duty and in their interest to carry on the business of the Company, your Board would feel far more pleasure in carrying on their work, feeling that they had the confidence of the shareholders, and although they do their best at present, still they would endeavour to do their double best. I forgot, gentlemen, to mention that perhaps some of the shareholders present would like to know what has been done in Scotland, and what our future prospects are. Well, if you will permit me, I will call upon Mr. Dickson, who has been so kind as to take upon himself the managing directorship of this department, and has given it great time, deep consideration, and anxious thought, and I think from his intimate knowledge of Scotland, and the mercantile parts of Scotland, the interests of shareholders are well left in his hands

Mr. DICKSON stated that at the time the company was formed they were aware that, irrespective of the Lane-Fox lamp, which was not such a great *pièce de résistance*, they had the Anglo-American Company's dynamo, as to which he held that a better one did not exist. They were carrying on operations in four of the principal towns in Scotland—Edinburgh, Glasgow, Dundee, and Aberdeen. At Edinburgh he believed the railway company would become an excellent customer of the Company. They had the privilege of running their wires along the side of the railway, which obviated the necessity of breaking up the streets, &c. At the Waverley station there were 32 lights, and he had put up one on the top of Princes-street, which showed the Town Council what they could do. They had gone to work as economically as possible, and he thought they gave their light as cheaply as any one could do the work. They were running the preliminary lights in Dundee, where they were giving the greatest satisfaction. They had offers of various contracts, and if the business of the Company was proceeded with, he did not doubt they would have plenty of work to do. Replying to a question, he added that the present contracts did not entail a loss.

Mr. MUSGRAVE repeated that he had still the greatest confidence in the Company. He held that shareholders should at once put their feet down on the attacks which had been made on their directors, and on the different companies.

The CHAIRMAN, in reply to other questions, stated that the Hammond Company were pushing the Ferranti machine, which was altogether different from that of this Company. The words in their license were "full license." The license was granted by the Anglo-American Corporation to the Scottish Brush Company, from which this Company sprang.

Mr. WILKINSON, in answer to Mr. Cunningham, stated that intimation had been sent to the liquidator of the Scottish Brush Company that this Company did make certain claims with respect to the misrepresentation as to the use of the Lane-Fox lamp.

On the motion of Mr. WALTER DALRYMPLE, seconded by Mr. IONIDES, the following resolution was unanimously carried:—"That the meeting, having heard the statement of the chairman, expresses its confidence in the Board of Directors, requests them to carry on the business of the Company, and to oppose all hostile actions brought by shareholders against the Company."

The proceedings then terminated with a vote of thanks to the chairman and directors.

ELECTRICAL ENGINEER.—An important Electric Lighting Company are OPEN to ENGAGE the services of an ELECTRICAL ENGINEER. To a thoroughly qualified gentleman most liberal terms will be offered.—Address, with references and full particulars of past experience, to ENGINEER, care of J. BURBIDGE and Co., 62, Moorgate-street, E.C.

Digitized by Google

SLIP

ELECTRIC LIGHT IN NEW ZEALAND.—Swan lamps are being successfully used in the reading room of Watson's Hotel, Dunedin.

ELECTRIC LIGHT IN HOTELS.—The great hall of Cannon-street Hotel will be lighted by the electric light from the commencement of the new year.

AN AMERICAN FAURE COMPANY.—The Faure Electric Storage and Light Company has been incorporated in New York with a capital of 2,000,000 dollars.

A CHEAP BATTERY.—It is stated that Dr. Brard has devised a cheap battery by turning to account the action of nitrates in igneous fusion on incandescent charcoal.

NEW COMPANY.—The Incandescent Electric Lighting Company has been formed with a capital of £250,000 in £1 shares. Mr. R. E. B. Crompton is one of the first subscribers.

EASTERN TELEGRAPH COMPANY.—The traffic receipts of this company for the month of November, 1882, amounted to £54,098, and to £49,829 in the corresponding period of 1881.

STUDENTS OF ELECTRICITY IN GLASGOW.—The number of members of the Glasgow College of Science and Arts Classes is—in electricity 103, and in electrical engineering, 76.

THE JABLOCHKOFF COMPANY.—The Jablochkoff Electric Light and Power Company, has appointed the secretary (Mr. Francis R. Reeve) to be secretary and general manager to the company.

DIRECT SPANISH TELEGRAPH COMPANY.—The traffic receipts of this company for the month of November, 1882, amounted to £1,998, against £1,810 in the corresponding period of last year.

ELECTRIC LIGHTING OF A TOWN HALL.—The new Town Hall, West Brighton, which is to be opened on the 13th inst., will be lighted by Swan lamps. The work is being carried out by Mr. Magnus Volk, of Brighton.

EASTERN EXTENSION TELEGRAPH COMPANY.—The traffic receipts of this company for the month of November, 1882, amounted to £32,591, and to £32,557 for the corresponding period of 1881, being an increase of £34.

DIVIDEND.—The directors of the Brazilian Submarine Telegraph Company have declared an interim dividend of 3s. per share, or 6 per cent. per annum, free of income-tax, for the quarter ended September 30 last, payable on the 23rd inst.

ELECTRICITY AND THE EVAPORATION OF FLUIDS.—Professor Freeman, of the Johns Hopkins University, of Baltimore, concludes, from a long series of experiments, that electricity is not demonstrably disengaged by the evaporation of fluids.

ELECTRIC LIGHT AT SALTLEY.—Messrs. Brown, Marshall, and Co.'s premises at Saltley, near Birmingham, are about to be lighted by Brush lamps. The work has been carried out by the Birmingham and Warwickshire Brush Electric Light Company.

THE MUNICH EXPERIMENTS.—We have received advanced proofs of an article in the forthcoming number of *La Lumière Electrique*, in which M. du Moncel treats the experiments by M. Marcel Deprez, at the Munich Exhibition, in a very exhaustive manner.

LIFE OF THE EDISON LAMP.—It has been stated recently that, out of 130 Edison lamps used to light a factory in the United Kingdom for some time past, only nine have broken since they were first put in, and that the remainder have been burning over 2,400 hours.

ROYAL SOCIETY.—The following paper was to have been read by Dr. A. Waller and Mr. A. de Watteville at the meeting of this Society on Thursday, viz.:—"On the Alterations of the Excitability of the Sensory Nerves of Man by the Passage of a Galvanic Current."

WEST INDIA AND PANAMA TELEGRAPH COMPANY.—The estimated traffic receipts of this company for the half month ended the 30th of November are £1,160, as compared with £2,254 in the corresponding period of 1881. The August receipts, estimated at £4,374, realised £4,362.

THE TELEPHONE IN GERMANY.—It appears that the telephone exchanges in 18 German cities comprise no less than 3,788 different stations. The total length of telegraph lines utilised by the telephonic service is 540 miles, giving a length of single wire equal to 4,017 miles.

GREAT NORTHERN TELEGRAPH COMPANY.—The traffic receipts of this company for November, 1882, amounted to £20,440; for the period from January to November, 1882, they were £223,720; for the corresponding months of 1881, £218,291; and for the same period of 1880, £219,922.

SOCIETY OF TELEGRAPH ENGINEERS AND OF ELECTRICIANS.—The annual general meeting of this society will be held at 8 p.m. on Thursday, the 14th inst. The following paper will be read:—"The Application and Extension of Telephonic Communication in Japan," by Thomas J. Larkin, member.

ELECTRIC LIGHTING AT ASHFORD (KENT).—The South Eastern Brush Electric Light Company will commence lighting the saw mills and joinery works of Mr. Draper Fowler, at Ashford, this week. Brush lamps will be used. This is the first time that Ashford has seen the electric light, so far as we know.

BRADFORD TECHNICAL EXHIBITION, 1882.—This exhibition, which was brought to a close last week, has been lighted since its commencement by the Yorkshire Brush Electric Light and Power Company of Leeds, who have been awarded a gold medal for their exhibit of electrical apparatus at the above place.

ELECTRIC LIGHTING AT BRIGHTON.—The Pavilion Committee of the Brighton Town Council have decided to light the ground floor of the Royal Pavilion with electricity. The first section of the work will comprise the fitting up of 600 Swan lamps. Mr. Magnus Volk, of Brighton, will carry out the installation.

ELECTRIC LIGHT AT JARROW.—Messrs. Palmer and Co., shipbuilders, of Jarrow, who have been lighting their works for some time past with Brush lamps, have now requested the Hammond Electric Light Company to put in a 40-light machine and more lamps. Previously they were employing a 16-light machine only.

CABLE REPAIRED.—The West India and Panama Telegraph Company have received advice of the repair, on 1st inst., of the cable between Jamaica and Ponce (Porto Rico). The Chord line, St. Croix-Trinidad, has also been repaired, so that the company are in direct communication with all their stations except Colon, Panama.

CUBA SUBMARINE TELEGRAPH COMPANY.—The number of messages passing over the lines of this company during the month of November was 2,005, estimated to produce £1,800, against 2,334 messages, producing £2,439 in the corresponding month of last year. The traffic receipts for the month of August, estimated at £2,550, realised £2,595.

Digitized by Google

To be Wound Up.—The Telephone Supply Company is to be voluntarily wound up, by resolution passed on the 13th November, and confirmed on the 30th of the same month. Creditors should send in their names and addresses, with particulars of their claims, to Mr. F. R. Grigg, 6, Lombard-street, E.C., the liquidator, before the 15th instant.

The Birth of the Secondary Battery.—In 1801 a Frenchman named J. N. Gautherot discovered that, when wires of platinum or silver had been used as the terminals of a battery for decomposing water containing some salts, they became capable of giving a current of their own for a short time, irrespective of the battery to which they were attached.

The Life of the Maxim Lamp.—As an addition to the figures regarding the life of the Maxim incandescent lamp, given in a recent note, we take the following slip from an American source:—"The ferry boat 'Jersey City,' belonging to the Pennsylvania Railroad, is lighted by the Maxim lights, and their record has been given as averaging 1,645 hours, and the lamps still burning."

Electric Lighting in Leeds.—We learn that the Yorkshire Brush Electric Light and Power Company, of 1, East-parade, Leeds, have secured a contract for the lighting up of the market place and principal streets of Dewsbury, Yorkshire, during the forthcoming Christmas holidays, and this Company is now putting down machines and erecting wires and lamps for running about 16 2,000 candle-power Brush arc lights.

The Ader Telephone in Belgium.—Messrs. Mourlon and Co., of Brussels, have erected Ader telephones in the offices of the chief officials of the Société Générale for aiding national industry, so that the heads of the various departments can communicate with one another. The same instruments are also to be erected in the large granite works at Quenast. We should think that our own quarry owners would find the telephone useful.

Electric Lighting in Sheffield.—The large premises of Mr. Davy, provision merchant, Fargate, Sheffield, have been lighted by 120 Swan incandescence lamps, which are fed by one of Siemens's W_2 alternate current machines. The local press, in commenting upon the installation, state that "Messrs. Tasker Sons and Company, by whom the whole of the arrangements have been carried out, are to be congratulated upon a success which has no parallel in this neighbourhood."

City and Guilds of London Institute.—Mr. C. W. Siemens, D.C.L., F.R.S., has consented to distribute the prizes and certificates gained by the successful candidates of the metropolitan centres at the recent technological examinations, as well as by the students of the City and Guilds of London Technical College, Finsbury, and of the City and Guilds of London Technical Art School, Kennington. The distribution will take place on Thursday evening, December 14, at seven o'clock, in Goldsmiths' Hall, Foster-lane, E.C.

Dynamos.—On Monday night Professor Sylvanus P. Thompson delivered the first of a course of three Cantor Lectures on this subject at the Society of Arts. The first lecture dealt with the history and classification of the dynamo, and was illustrated by diagrams. The second and third lectures, to be delivered on the 11th and 18th inst., will treat of the dynamo in practice, and the dynamo as a motor. We shall reprint these lectures, with illustrations, in the usual course on their appearance in the *Journal of the Society of Arts*.

Electric Lighting in London.—The Lambeth Vestry are going to devote a special meeting to the consideration of the electric light one month hence. The Fulham Board of Works have resolved "That the consent of the Board be not given to any application for a license under the Electric Lighting Act, 1882, unless the draft license, as proposed by the applicants, has been deposited at the offices of the Board at least fourteen days before the day appointed for the special meeting convened for the purpose of giving such consent."

Illness of the Postmaster-General.—At the request of Mrs. Fawcett, the Secretary of the Post Office has issued a notice conveying her grateful thanks for the expressions of sympathy which she has received from the postal and telegraph staff in different parts of the United Kingdom. It is impossible for her at present to individually acknowledge their kindness, but she is confident they will not doubt that she heartily appreciates it. At the time of our going to press Mr. Fawcett's condition, though still precarious, was more satisfactory.

Newcastle-on-Tyne.—Although the requisite notices had been issued, the Town Council on Wednesday, resolved, by a majority of 29 to 15, to abandon for the present the application to the Board of Trade for a provisional order authorising them to supply electricity for all public and private purposes within the area of the city and county of Newcastle. It was stated that Mr. Chamberlain was anxious to insert a clause in the order compelling the corporation to make a trial in some district of the electric light, and this proposal evoked much opposition.

The Edison Lamp on Board Ship.—The Edison system, as recently applied to the "Tarawera" steamer, belonging to the Union Company of New Zealand, was exhibited on board that ship in Greenock Harbour last week. The "Tarawera" has just been built by Messrs. Denny and Co., of Dumbarton, and is one of the first ships belonging to this side of the Atlantic which has been fitted with the Edison lamps. The lights, to the number of 150, are scattered about the ship, in the state rooms, saloons, shaft tunnel, &c. The current is supplied by an L dynamo, driven by a Brotherhood three-cylinder direct-acting engine. The usual Edison fittings, fusible plugs, &c., have been employed. We hope to be able to furnish our readers with a few more details of this work before long.

Electric Lighting in the City.—At the last meeting of the Court of Common Council, Mr. Felton (the Chairman of the Commissioners of Sewers) said he was not at the moment able to state the exact area now lighted electrically, but the length of thoroughfare lighted by the Brush Company was 1,648 yards, and by the Maxim-Weston Company 1,703 yards. The whole matter was now under the consideration of the Commissioners of Sewers, and he believed—it was only his opinion—but he believed it was the intention of the Commission to have the whole of the City lighted by the electric light. The subject would come before the Commission at its next meeting, and the question would be whether the Commission would allow the various companies to compete for the lighting, or whether the City would undertake the lighting itself.

Electrical Exhibition at Vienna.—This exhibition, which was to have been opened this year, but was postponed on account of the Munich Exhibition, will take place next year. It is intended to open it on the 1st August, 1883, and to close it on the following 31st October. It will be held in the same buildings as the 1873 Exhibition. Demands for space should be sent in before the 1st January next to the

Digitized by Google

Organising Committee, Vienna. Exhibitors will have nothing to pay for space, nor for the power required for general lighting. The power required by an exhibitor for his own exhibit, however, will be supplied to him at the rate of 20 kreuzers per horse-power per hour. Apparatus exhibited and not patented in Austria-Hungary will be protected as if patented up to the end of 1883, and should be specially mentioned to the committee. There will be no rewards.

Strand District Board of Works.—An influential body of members of this board visited the works of Messrs. Verity and Sons, on Wednesday night, for the purpose of inspecting the Edison electric lighting installation on the premises of the above named firm, in King-street, Covent-garden. The display was a most brilliant and artistic one, Mr. Edison's incandescent lamp being shown to the utmost advantage in every conceivable situation and pattern. The electrolier manufactured by Messrs. Verity, and exhibited at the Crystal Palace, which we illustrated at the time in these pages, was far excelled in beauty of design and richness of material by some that were shown on this occasion. For every purpose of indoor lighting, whether appended to simple brackets or worked into the design of costly electroliers, the lamps were effective and agreeable. The deputation seemed highly satisfied with the installation.

Society of Arts.—Since the commencement of the present session the society's meeting room has been lighted by means of electricity. A Siemens dynamo is employed, driven by an eight-horse power Crossley gas engine. Nearly the whole cost of these was defrayed by subscriptions from a few past and present members of the society's council. The lamps used are those of Edison, and there are at present fifty of them in the room. The chandeliers now in use have been lent by Messrs. Verity, who are constructing chandeliers to be permanently fitted now that the number of lights to be used has been decided upon. Temporary fittings have been put up in the council room, and the result having been proved satisfactory, it is in contemplation to arrange for the lighting by electricity of this and other parts of the building. At first some difficulties were found in getting sufficient steadiness in the light, but these have now been overcome by Messrs. Crossley.

Leeds Town Council and Electric Lighting.—In answer to a recent letter from the town clerk of Leeds, asking whether, in the event of the Town Council applying for an order, a clause would be inserted therein compelling them to supply the electric light, and pointing out that such clause should be of a permissive, and not a compulsory character, Mr. Chamberlain replied that "The Board of Trade have no hesitation in saying that, in their opinion, it was the intention of Parliament that the schemes to be sanctioned by licenses or provisional orders under the Act should be *bonâ fide* schemes for definite undertakings, and not schemes containing general powers authorising a corporation or a company to light all or any portion of a town if, when, and as they might in their discretion think it desirable to do so. It would further, in their opinion, be clearly contrary to the intention of Parliament to sanction a scheme which merely enables the promoters to appropriate an area of supply to the exclusion of other applicants."

Electric Lighting in Chelsea.—On Tuesday the Chelsea Vestry considered the question of electric lighting as set forth in a lengthy report from their surveyor, Mr. G. H. Stayton, C.E. We shall allude to this report, a copy of which we have been favoured with, at greater length in our next issue. We may say here, however, that the vestry unanimously adopted the following recommendations with which Mr. Stayton concludes his report, viz.:—"1. That at present it is not desirable for the vestry to apply for a license or provisional order. 2. That it is not desirable to consent to any application for a license until the draft shall have been submitted to, and has received the approval of, the vestry. 3. That it is desirable to support the application of any company who may appear most likely to carry out the undertaking in a satisfactory manner, and who will agree to such of the suggested conditions as the Board of Trade may approve and that the Electric Lighting Committee and the surveyor be empowered to enter into the necessary negotiations for effecting that object. 4. That the solicitors be instructed to watch the progress of the applications for provisional orders, and to take all necessary steps to oppose the same until satisfactory conditions are obtained."

Thunderstorms at Great Heights.—Being desirous of examining the air at great heights in order to ascertain the proportion of ammonia present, as well as some facts as to atmospheric nitrification, Messrs. Muntz and Aubin recently examined the record of thunderstorms kept at the Pic du Midi observatory, some 9,590 feet above the level of the sea. Of the 184 thunderstorms observed from 1873 to 1882 they found that only 23 had been produced at a height above 7,700 feet (where the original station of Plantade is situated). In the latter the summit of the Pic was surrounded by clouds, whence the discharges came. It may be said in general that in the Pyrrenean region the violent electric phenomena of thunderstorms never exceed a height of 10,000 feet (3,000 metres), and that, consequently, the formation of nitrates under the influence of electricity is below this limit. Atmospheric nitrification seems to be chiefly produced in the zone between the sea level and the mean height of clouds. This absence of fine powders of nitrates, the authors also remark, certainly contributes to the remarkable transparence of the air in high regions, and shows that the plants on high mountains and the soil they have formed can only obtain their nitrogenised matter from the ammonia of the air.

Electric Lighting of Brunn Theatre.—During the last week in November several gentlemen interested in science visited Brünn for the purpose of examining into the details of the Edison system as in use there. Amongst the visitors have been the Scientific Society from Vienna and the Imperial Commission from the same city. The Commission were so satisfied with the light that they will introduce it into the new Imperial Opera House as well as the Burg Theatre in Vienna. The lighting of the grand dancing hall in the Emperor's castle was also talked of. Professor Columbo and Signor Buzzi, from Milan, also visited the theatre, with the object of inspecting the system of regulation employed, in order to introduce it into the Scala Theatre at Milan. The Professor, we believe, will use no less than 3,000 lights for the stage alone. In connection with the opening night, a correspondent sends us the following account of an amusing incident which occurred. He says: "Mr. Rau had a large 'bouquet' made, and fixed an Edison lamp in the centre, connected with two invisible wires, which ran from underneath the stage. It was then presented to one of the leading stars, and the moment she received it connection was made and the lamp burned. The applause was terrific. It brought the house down."

The Telephone throughout the World.—The Compagnie Internationale des Téléphones has just published some interesting statistics relating to the position of telephone exchanges throughout the world on the 1st October, 1882. The telephone is more freely used in America than

Digitized by Google

elsewhere, for there no rates have to be paid to State or town authorities. New York has 4,060 subscribers; Chicago, 2,726; Cincinnati, 1,880; Boston, 12,325; San Francisco, 1,300, &c. Some of these figures refer to May. There are now in the United States more than 100,000 subscribers, and certain small towns, with population less than 1,000, yet have 30 to 50 telephonic subscribers; some even more. As regards the absolute number of subscribers, Paris comes third, after New York and Chicago; it had on October 1 no fewer than 2,422 subscribers, while London had only 1,600, Amsterdam 700, Stockholm 672, Vienna 600, Berlin 581, Brussels 450, Turin 410, Copenhagen 400, Mexico 300, St. Petersburg 145, and Alexandria 118. While the annual subscription is 600f. in Paris, 500f. in London, and 400f. in the provincial towns of France, it descends to 300f. and 200f. in Belgium, 135f. and 130f. in Italy, and only 120f. in Switzerland. If we calculate for each town the ratio which the subscribers to telephone exchanges bear to the total number of inhabitants, we find that small American towns are far ahead, for in many there is one telephone to every twenty inhabitants; in Chicago and in Zurich, the proportion is about one per 200; in New York, one per 500; in Brussels, one per 800; in Paris, about one per 1,000; in Berlin, one per 2,000; in London, one per 3,000; and in St. Petersburg, only one per 4,000

The Magnetic Storm in America.—The *Operator* gives an account of the storm which occurred on the 17th November, from which we make the following extracts:—"The storm centre seemed to be along the valley of the Mississippi, and at its greatest severity in those parts of the country north of the latitude of Washington. The only wires that could be used at all were those connected in metallic circuits. All the cables and wires that touched the ground were absolutely useless. . . . At Chicago the intensity of the currents appears to have been greatest. The switch-board of the Western Union office was on fire a dozen times during the forenoon, and half-a-dozen keys were fused by the current, the points burning up even when parted to their farthest limits. At noon but a single wire out of fifteen between Chicago and New York was in operation, and it was frequently interrupted. The disturbance was greatest on east and west lines. Washington and Baltimore offices succeeded in working with each other for a while by means of the earth currents, as did also Washington and Norfolk, Cincinnati and Columbus, and Cincinnati and St. Louis. The longest circuit operated by the earth currents alone was that between Bangor, Me., and North Sydney, Cape Breton, 700 miles long. . . . A singular phenomenon was witnessed at the office of the Domestic Telephone Company in Newark, N.J. From 10 o'clock in the morning up to noon the drops on the annunciators, which indicate that a subscriber wishes to use the telephone, kept falling by the dozen at a time. At times every drop on the board would fall at once; at other times a whole row would give away, and at others only a dozen or so. No sooner would they be restored to their proper position than drop, drop, drop would be again heard. The superintendent said that such phenomena have been known before, but he could recall no cases where they lasted for so long a time. In the Cleveland, Ohio, exchange as many as fifty indicators dropped at one time. Similar experiences were had in exchanges in other parts of the country. In Milwaukee the novel experiment was made of connecting an Edison incandescent lamp in the circuit of one of the telegraph wires affected by the earth currents. According to the Edison Company's agent at Milwaukee the lamp glowed with a light equal to about thirty candles. This, Mr. Edison says, would indicate a current such as would be produced by the expenditure of eight horse powers [Query.—Ed. *E.*]. Some faint idea of the enormous energy of the storm may be gathered from this experiment, for if there had been 10,000 wires, each would probably have exhibited the same effects, and yet there is reason to believe that but a small portion of the currents traversing the earth's crust is diverted to the wires."

Provisional Orders.—The following notices of intention to apply for provisional orders have been made public in addition to those given in a Note in our last issue:—The Metropolitan Brush Electric Light and Power Company have given further notices relating to the following Metropolitan parishes and districts:—St. Pancras, Islington, Greenwich, Lewisham, Hornsey, Highgate, Southgate, Tottenham, Edmonton, Leyton, Hampstead, Willesden, Hendon, Finchley, Wandsworth, Wimbledon, Newington, St. George-the-Martyr, St. Saviour's, City of London, Clerkenwell, St. Luke's, St. Olave, Bermondsey, Rotherhithe, Hackney, Bethnal Green, Shoreditch, Fulham, Chiswick, Acton, Ealing, West and East Ham, and Wanstead.—The Edison Electric Light Company have given a general notice as regards the City and districts of London.—The Swan United Electric Light Company have given notices for Victoria district, South Kensington district, Hanover-square district, and the Strand district.—The Pilsen-Joel and General Electric Light Company have given notices, including Holborn, St. Giles's (Bloomsbury), St. Pancras, and the City of London.—The Incandescent Electric Lighting Company have given notices for Redditch, Birmingham, Northfield (Worcestershire), Reading (Berks.), and Walsall (Staffs.).—The Union Electric Light Company have given notices as to Brighton and Sheffield.—The South Staffordshire Electric Light Company have given notices relating to Walsall, Balsall Heath, Saltley, and Aston (all three suburbs of Birmingham), West Bromwich, Wednesbury, Darlaston, Wolverhampton, and Dudley.—The Lancashire and Yorkshire Electric Lighting Company, of 5, St. James's-square, Manchester, have filed notices including Stalybridge (Yorks.), Wakefield, and Hyde (Cheshire).—The Great Western Electric Light and Power Company have given notices as to Newport (Mon.), Gloucester, Cardiff, and Cheltenham.—A notice as to Sunderland has been registered by the North Eastern Electric Light and Power Company, of 61, John-street, Sunderland. Similar notices have also been given by the following corporations, in addition to those previously recorded by us, viz.:—Wigan, Stockton, Southport (Lancs.), Stockport (Cheshire and Lancs.), Bradford, Leamington, Bootle-cum-Linacre (near Liverpool), Burton-on-Trent, Blackpool (Lancs.), Sheffield, Accrington (Lancs.), Oldham, Batley (Yorks.), Liverpool, Chichester, Bolton, Birkenhead, Colchester, Preston (Lancs.), Reading, Nottingham, Brighton, Plymouth, Keighley (Yorks.), Manchester, Truro (Cornwall), Newcastle-on-Tyne, Leeds, Swansea, St. Helen's (Lancs.), Norwich, Portsmouth, Dover, Bath.—The following local authorities have filed notices as regards their own districts, viz.:—Beckenham (Kent), Nelson, Farnworth, Barton, Eccles, Winton and Monton, and Todmorden (all in Lancs.), East Stonehouse (Devon), Richmond (Surrey), Birkdale (Lancs.), Cambridge, Ealing (Middlesex), Altrincham (Cheshire), West Hartlepool, Chadderton (Lancs.), Weston-super-Mare, St. Pancras (London, N.), Buxton (Derbyshire), Ulverston (Lancs.), Aspull (Lancs.), and Hucknall Torkard (Notts.).

The Commissioners of Sewers and Electric Lighting.—At a meeting of the Commissioners of Sewers, held at the Guildhall on Tuesday last, Mr. Moore moved, "That the

Digitized by Google

following resolutions passed at the special Court on November 21st last in regard to electric lighting, viz., 'That, whilst the Commission is now in favour of electric lighting in the abstract, it is advisable to allow all further experiments to be conducted at the risk of the lighting companies, and not at the expense of the ratepayers. That the Remembrancer be instructed to appear on the applications of the electric lighting companies, and secure clauses protecting public and private rights,' be, and the same are hereby, rescinded." Mr. Moore followed up his resolution by some remarks, from which we extract the following:—He said, "There were three courses open to them. The first was to obtain a provisional order. The effect of their proceedings at the last Court was to destroy the possibility of their obtaining a provisional order, but they could adopt the second method, which was to proceed by license. A provisional order was for 21 years; a license was only for seven years; but having a license it was possible for them to apply for a provisional order. At the last meeting alarming representations were made as to the heavy liabilities and costs they were likely to incur. They could see the worst of it from the results of the experiments into which the Commissioners had hitherto gone. They had it on the authority of the engineer that the actual cost of lighting the three districts they had hitherto experimented upon was £8,060. Of that £3,670 was the cost of works. Instead, therefore, of getting into half a million, or three millions, as was suggested, they could form an idea what the outside cost of the works would be in the event of the Commission seeking to extend them still further through the City. The actual cost of the light for twelve months over the area stated, calculating the cost of the plant, was £4,390, and the quantity of light which the public had received for that sum of money was 103,000 candles. The total illuminating power of gas over the same district was 6,000 odd candles, that was to say, they had sixteen times the amount of light for this district. The cost of electricity was £4,390, the cost of gas for the same district was £2,002. They had had sixteen times the amount of light, and had paid twice the cost of gas. He had consulted several eminent electricians, and all considered that the lighting of the City by electricity was most feasible and practicable. He, therefore, hoped they would, without hesitation, agree to his motion to rescind." The motion was duly seconded, and thereupon ensued one of those lively discussions, which are very amusing reading, but somewhat too full of "exuberant verbosity" for reproduction here. Suffice it to say that the motion was carried by 31 to 23, or a majority of 8; it was then found, however, that the number of members present was not sufficient to rescind the resolutions passed at the previous meetings, and an uproar at once arose, in the midst of which the chairman vacated his chair and the room. In the end the clerk was requisitioned to call a special meeting to consider the matter.

Electric Lighting.—Deputation to Mr. Chamberlain.—On Tuesday last a deputation representing the important corporations of England and Scotland had an interview with Mr. Chamberlain at the Board of Trade to urge upon him the importance of making the use of the electric light permissive, and not obligatory. Mr. Arnold Morley, M.P., introduced the deputation.—Mr. Littler, Q.C., stated the views of the deputation. He said the corporations did not take their action from any spirit of hostility to the introduction of the electric light, but they thought that on the principle of local self-government they should be allowed to exercise a discretion. The corporations were not desirous of admitting the companies otherwise than as their agents. The corporations were not averse to the electric light, as had been suggested in some of the public prints, but they wanted a discretion in the matter. Their constituents objected to having to spend large sums of money or else be regarded as defaulting. —Mr. Chamberlain, in reply, said he would take that opportunity of dispelling some misapprehension as to the action of the Board of Trade in this matter of electric lighting. At the same time he would not express any definite conclusion on the points raised until he had had further time to consider them. Mr. Chamberlain quoted certain sub-sections of the Act, and said that there were other proofs which to his mind showed that Parliament intended that no obstacles should be placed in the way of a full development of electrical operations, and he did not think that that object would be attained if it were placed in the power of a local authority, not only at the present moment but for a time during which great improvements might be made in these sciences, to keep out all other and possible competitors without undertaking at the same time to do anything themselves. What Parliament felt was this—that in the case of electricity there was a great danger that corporations and local authorities, through a desire to spare the ratepayers, would be disposed to delay experiments which might be necessary. Parliament, therefore, he thought, did intend that such a condition should be laid down by the Board of Trade as would prevent that evil; and it endeavoured to guard against the danger by the imperative conditions which it had attached to the granting of provisional orders and licenses, and he confessed the alarm which had been expressed in some quarters as to the possible intrusion of companies into their district seemed to him to be altogether exaggerated. With regard to the conditions under which alone these companies could be intruded, he was disposed to attach all possible weight to what Mr. Littler had said as to the uncertain condition of the whole subject at the present time. He did not see how the Board of Trade could make any distinction between corporations and companies in reference to provisional orders containing specific information as to the area of supply, as to the nature of the works, as to the amount of capital to be expended, &c. If the Board of Trade granted anything like the freedom which was asked for by corporations to companies, the evil would be very great in the case of those corporations which did not ask to supply themselves, but which were willing that the Act should be carried out by companies in their district. It was certainly their intention not to proceed without hearing everything that could possibly be said on all sides of the question. If an application were made by the company the Board of Trade would hear everything that the corporation had to urge against the grant to the company, even though the corporation stated that it was not itself prepared to enter upon the new field of supply; in fact, they would hear any general objections to a company going into the district, and no license would be granted until all the representations of the local authority had been heard against it. The policy of allowing companies to occupy a district (with the safeguards taken) was perfectly legitimate; and it was impossible for them to obtain more than a fair and reasonable profit. Then as to the breaking up of the streets, there was an express provision in the Act which would enable corporations to insist upon the insertion of a clause in the provisional order giving the corporation the power of breaking up the streets for, and at the expense of, the private undertakers who might undertake the supply of electricity.—Mr. Arnold Morley having thanked the right hon. gentleman, the deputation then withdrew.

THEORY OF MAGNETO AND DYNAMO MACHINES.

XXI.

We ought now, perhaps, to enter on the ring type of armature devised by Pacinotti, and applied in the Gramme and a host of other machines; but a general understanding of the first principles involved in it is, we believe, pretty widely spread, and as a quantity of very interesting matter is pressing to be discussed, the complete investigation of the principles of the Gramme armature may be left over for a time.

What we shall now proceed to discuss is the action of a dynamo considered as a self-exciting machine.

We know how the E.M.F. is generated in the armature when it revolves in a magnetic field, and the data necessary to be given in order to calculate its amount; we have now to consider how the magnetic field is produced by means of a portion of this same E.M.F., and on what the efficiency of a dynamo as a current producer depends.

Now, there are two well-known methods of exciting the field magnets of a dynamo: the first is to send the whole current round them as well as through the external circuit, which is the ordinary or direct-current method; and the other is to send only a fraction of the whole current round the field magnets, but to apply to them the same E.M.F. (instead of the same current) as is applied to the external circuit; this method being known as the divided circuit or shunt method.

A dynamo excited according to the first plan is called an ordinary or *series dynamo*. Excited according to the second plan, it is called a *shunt dynamo*.

The theory of the latter is in some respects the more simple, and in many respects the more satisfactory; moreover, shunt-excitation is believed by many persons (the writer included) to be a better and more economical mode of working than excitation by total current. We will discuss it first.

Theory of the Shunt-dynamo.

We shall use the alphabet in the following sense, without regard to the meanings hitherto attached to the letters in these articles:—

a shall stand for the resistance of the armature wire from brush to brush, in ohms;

A for the current flowing through the armature wire, in amperes;

b shall be the resistance of the field magnet wire;

B the current passing through it;

r is to be a resistance equivalent to the external circuit, whether this consists of a simple wire or not;

C is the current in the external circuit;

E is to mean the total E.M.F. generated by the revolution of the armature, in volts;

e the E.M.F. applied to the external circuit, or the difference of potential between the terminals of the machines.

The only explanation needful concerning these symbols is with reference to r. In many cases the term "resistance" is not properly and simply applicable to the external circuit at all, as, for instance, if it contain secondary batteries or arc lamps; only when the circuit contains nothing but simple wires, incandescent lamps, or other such metallic conductors can the term resistance be directly and correctly applied. But, nevertheless, the ratio of $\frac{e}{C}$ has a certain definite value at every instant, though often its value is very fluctuating (notably so in the case of an arc lamp, where the *product* eC is, or should be, much more nearly constant than the *ratio*), and it is highly convenient to be able to speak of this ratio as the external resistance r. The meaning of r in every case is, therefore, accurately and completely defined as $\frac{e}{C}$.

This being premised, how many relations does Ohm's law give us among the above quantities? These:

$$e = r\,C \quad . \quad . \quad . \quad . \quad \text{(i)}$$
$$e = b\,B \quad . \quad . \quad . \quad . \quad \text{(ii)}$$
$$E - e = a\,A \quad . \quad . \quad . \quad . \quad \text{(iii)}$$

and common sense gives us one more, viz.:

$$A = B + C \quad \ldots\ldots \quad \text{(iv)}$$

What does Joule's law tell us about the heating of the different circuits? The following:—(a watt being $\frac{1}{746}$th of a horse-power)

Power expended in heating armature $= a\,A^2$ watts (v.)
Power expended in heating field magnet $= b\,B^2$ „ (vi.)
Power expended in external current $= r\,C^2$ „ (vii.)

The last of these is the useful power, the two former are the waste.

The electric *efficiency* of the shunt-dynamo is therefore—

$$\frac{\text{useful power}}{\text{total power}} = \frac{r\,C^2}{a\,A^2 + b\,B^2 + r\,C^2} \quad . \quad . \quad . \quad \text{(viii.)}$$

I call it the *electric* efficiency, because we do not here consider the *mechanical* waste of power in heating the bearings or the strap, but simply and solely the ratio of the power obtained as current in the external circuit to the total power obtained as current altogether. Observe that we are reckoning *the whole* of eC or rC^2 as useful power, although in practice part of r will consist of leading wires in which some waste heat will be produced. But it is obviously undesirable to heat your leading wires; and either they may be so thick that the heating is inappreciable, or else they may be as thick as is consistent with economy of capital, and the waste in them after that may be considered so far unavoidable as to be, to all intents and purposes, part of the useful effect.

When we come to the subject of the transmission of power, the resistance of the leading wires will be of extreme importance, and then we will fully take them into account.

The useful power and the total power are two things of such vital importance that we will introduce symbols for them, and will write their values in a variety of equivalent ways. The first call p, the second P, so that the ratio $\frac{p}{P}$ is the efficiency.

$$p = e\,C = r\,C^2 = \frac{e^2}{r} \quad . \quad . \quad . \quad . \quad . \quad \text{(ix.)}$$

$$P = E\,A = e\,A + a\,A^2 = e\,(B + C) + a\,(B + C)^2$$
$$= b\,B^2 + r\,C^2 + a\,(B + C)^2 \quad . \quad . \quad . \quad \text{(x.)}$$

The expression for the efficiency given in equation (viii) is by no means in its simplest form, and we will proceed to simplify it by help of equation (i) and (ii) combined. Referring to (i) and (ii) we perceive that they give us the simple, but very useful, fact that

$$\frac{B}{C} = \frac{r}{b} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad \text{(xi)}$$

and if we substitute this value of B in (viii), remembering also (iv), the currents all cancel, leaving only resistances, thus—

$$\text{Efficiency} = \frac{p}{P} = \frac{r\,b^2}{a\,(b + r)^2 + b\,r^2 + r b^2} \quad . \quad \text{(xii.)}$$

A still simpler thing to work with, than this ratio of the useful power to the total, is the ratio of the waste power to the useful; and this I shall call the *waste-ratio* of the dynamo. Its value is

$$\text{waste ratio} = \frac{\text{waste}}{\text{useful}} = \frac{a\,(b + r)^2 + b\,r^2}{r\,b^2}$$
$$= \frac{a}{r}\left(1 + \frac{r}{b}\right) + \frac{r}{b} \quad . \quad \text{(xiii.)}$$

This is an exceedingly simple and handy expression for a quantity which it is desirable to get as small as possible. If we determine the conditions necessary to make this a minimum it will be obviously the same thing as finding what will make the efficiency a maximum.

Problem 1.—For a given shunt-dynamo, what is the most economical value of the external resistance? In other words, through what external resistance shall we get the greatest effect? And what is, then, the maximum efficiency?

Ans.—By simply differentiating (xiii.) with respect to r, the best value of the external resistance is found to be

$$r = b\sqrt{\frac{a}{a + b}} \quad . \quad . \quad . \quad . \quad \text{(xiv.)}$$

Digitized by Google

This is the formula given by Sir Wm. Thomson at the York meeting of the Brit. Assoc.

Inserting this value of r in (xiii.) and in (xi.) we get: the least possible waste ratio for the given dynamo

$$= \frac{2a}{b}\left\{1 + \sqrt{\left(1 + \frac{b}{a}\right)}\right\} \quad . \quad . \quad . \quad \text{(xv.)};$$

or the greatest possible efficiency of the given dynamo

$$= \frac{b}{2a + b + 2\sqrt{a}\sqrt{(a+b)}} \quad . \quad . \quad \text{(xvi.)}.$$

PROBLEM 2.—In constructing a dynamo, what is the most economical relation between the resistances of its field magnet wire and its armature?

Ans. By simple inspection of (xii.), or (xiii)., or (xv.), or (xvi.), the efficiency is seen to increase as the ratio $\frac{b}{a}$ increases, and to have no maximum; hence the greater the quantity of wire wound on the field magnets and the thicker the wire on the armature the better for economy. It would be very wasteful to have b only five or six times a; if b is as much as 400 times a there will be very little waste, but there will be still less if b is, say, 4,000 times a.

Assuming, therefore, that the given dynamo has as large a ratio $\frac{b}{a}$ as it ought to have, the equations xiv. and xvi. can be written in approximate, but quite sufficiently accurate, and very easily applied, forms thus:

$$\text{best value of } r = \sqrt{a\,(b-a)}. \quad . \quad . \quad \text{(xvii.)};$$

maximum efficiency corresponding

$$= 1 - 2\sqrt{\frac{a}{b}} + 2\frac{a}{b} \quad . \quad \text{(xviii.)}.$$

THE ELEMENTARY PRINCIPLES OF ELECTRICITY.

III.

DEF.—A surface is said to be *level* when a heavy body has no tendency to pass from any one point to any other upon the surface.

A horizontal plane is, practically, a level surface if its dimensions are small. Over an extended area a level surface conforms to the general form of the earth. Thus a complete level surface, drawn through any point, is approximately a spheroid whose centre is coincident with that of the earth.

The test practically employed in order to determine whether a surface is level or not consists in observing whether a mobile liquid has any tendency to flow from one point to another of the surface. For this purpose a spirit level is employed. A spirit level consists of a glass tube very slightly curved, and mounted with its convexity upwards. The tube is nearly filled with spirit, leaving only a small bubble. The bubble always occupies the highest point of the tube, that is, the centre of the bubble lies at that point of the tube where the tangent is horizontal. If the instrument is properly mounted the centre of the bubble will coincide with the middle of the tube, however the instrument may be turned in azimuth, so long as it lies on a horizontal plane; but if the level is placed on a plane which is not horizontal, the spirit will flow towards the lower end of the instrument, and the bubble occupy the highest portion. Thus the tendency of a heavy fluid to pass from points at a higher level to those at a lower level is practically utilised to test whether or not a surface is a *level* surface.

Spirit levels, as employed by carpenters, builders, &c., determine whether small plane surfaces are horizontal. As employed in the survey of a large tract of country the spirit level enables the surveyor to follow a curved surface which coincides with what would be the surface of still water—if water were present—but which cannot be regarded as a plane surface except over a very small area, and then only approximately so.

If a vertical straight line were erected in London, and points marked off upon the line at successive distances of one foot, and if level surfaces were drawn through these points their form would agree generally with the surface of the ocean supposed smooth, and they would cut the more elevated portion of the earth's surface in *contour* lines. But though the vertical distance between successive surfaces in London was exactly one foot, it would be found that the distance did not remain the same in other latitudes. At the poles it would be less than one foot, and at the equator more than one foot, just as the earth's polar radius is less than the radius through London, while the equatorial radius is greater.

The law by which the distances between successive surfaces would be regulated is the following:—*The work done on a given portion of matter in falling from any surface to the next would be the same at all points, and therefore equal to that done in falling between the same two surfaces in London.*

Hence, where gravity is strong, as at the poles, the distance between the successive surfaces will be small, but when gravity is weak, as at the equator, the distance will be proportionally great. As we recede from the earth's surface, these local differences will diminish, and the general form of the surfaces will approach more nearly to that of a sphere.

If we define a foot-pound as the work done by gravity on a pound in falling vertically through one foot to the sea level (Trinity high-water mark) in the latitude of London, thus making it an absolutely constant unit of work, instead of a variable unit as it is generally defined to be, then the work done on a pound in falling from one of our hypothetical level surfaces to the next will be everywhere a foot-pound, provided the surface to which the pound falls be that which passes through the Trinity high-water mark in London.

But if the distance between successive surfaces in London be in all cases a foot, the work done on a pound in falling from one surface to the next will diminish as we ascend, in consequence of the diminution of gravity. We may, however, so regulate the distances between successive surfaces in London that the work done may, in all cases, be a foot-pound. The distance between successive surfaces will then increase as the intensity of gravity diminishes with increased altitude, but the system of surfaces will possess the simple property that a foot-pound of work will be done on a pound in falling from each surface to the next in succession, whatever be the locality in which the fall takes place, and whatever be the elevation above the sea.

These surfaces may be numbered consecutively from the sea level, which may be regarded as zero. Surfaces below the sea level may have negative numbers assigned to them. The level of a point lying on one of these surfaces will then be represented by the number assigned to the surface, and the level of a point lying between consecutive surfaces will be represented by a fractional quantity. On this system the level of a point is represented by the number of foot-pounds of work done on a pound in falling from the point to the sea level, that is the surface whose level is zero. Levels thus determined may be said to be measured with the *foot-pound rule*. They differ from levels measured with the *foot rule* on account of the variation of gravity. On the foot-pound system the difference of level between two points is equal to the number of foot-pounds of work done by gravity on a pound in falling from the first point to the second, whether the points lie in the same vertical or not.

It should be noticed that the *foot-pound* as above employed is not the foot-pound as ordinarily defined, but is a constant unit not varying with the intensity of gravity in different localities. We might have drawn our surfaces so that the work done on a gramme in descending from each surface to the next was always equal to one erg, and the set of surfaces would then have corresponded to the C.-G.-S. absolute system of units.

If it is desired to measure the depth of a mine for the purpose of estimating the cost of pumping water from it, or the height of a mountain lake, for the purpose of estimating its value as a source of power, it is clear that the intensity of gravity ought to be taken into account, and thus it is the *foot-pound rule* and not the *foot rule* which ought, theoretically, to be employed in the measurement.

A method (which is practically possible) of employing the foot-pound rule for the measurement of the difference

Digitized by Google

of level between two points is the following:—Connect the two points by a tube filled with water, and attach a pressure gauge, which registers in *absolute* measure, to the lower end of the tube. The registration of the gauge will indicate the difference of level between the ends of the tube on the *foot-pound* system.

Henry Cavendish pointed out that electricity, in many of its properties, resembles an incompressible fluid, so that there are many analogies between the behaviour of electricity in conductors and of water in tubes or other vessels.

If a heavy fluid tend to pass from a point A to a point B, then A is said to be at a higher level than B. If positive electricity tend to pass from one point to another, the first is said to be at a higher *potential* (or electric level) than the second.

The electric *potential* is in the theory of electricity what level is in the theory of gravitation.

Def. The *potential* of a conductor is its electric condition with reference to its power of communicating electricity to, or of receiving electricity from, other conductors.

As thus stated, the definition of electric potential is similar to that of temperature in the theory of heat. But, in the case of electric potential, we can do what we cannot do in the case of temperature, that is, explain at once how electric potential may be estimated *quantitatively*. In this respect electric potential resembles level in gravitation; we have only to replace the unit of mass by the unit of electricity.

Def.—The difference of potential between two points is the number of units of work (*ergs*) done by electric forces on the unit of (positive) electricity in passing from the first point to the second.

Def.—An *equipotential* (or *level*) surface is a surface such that electricity has no tendency to pass from any one point to any other point upon the surface.

As in the case of gravitation, the zero of electric potential (or level) may be arbitrarily selected. For our zero of level we selected the Trinity high-water mark, a purely arbitrary zero. For the practical zero of electric potential it is usual to take the potential of the earth, which for many purposes may be regarded as sensibly uniform. In purely theoretical treatises the zero of electric potential is that of a point *infinitely* distant from all electrified bodies. Taking the potential of the earth as the zero of electric potential it follows that:—

The potential of a point is the number of units of work (ergs) done by electric forces and the unit of (positive) electricity in passing from the point to the earth.

This is, of course, equal to the number of units of work done against electric forces by an agent bringing the unit of electricity from the earth to the point, for otherwise "*perpetual motion*" could be shown to be possible.

It is very important to observe that *level* is an *attribute of a point* in the neighbourhood of the earth whether there be any *matter* at the point or not. Thus, in our foot-pound system of measurement, if we say that the level of a point is 1,000, we imply that 1,000 foot-pounds of work would be done on a pound in falling from the point to the sea level, but we *do not imply* that there is a pound or any other quantity of matter in the *immediate* neighbourhood of the point, whose situation with respect to the earth is alone sufficient to confer upon it the attribute of level.

Similarly, in the case of electricity, *potential* is an attribute of a point in space, and it does not follow that there is any electricity *at*, or *in the immediate vicinity of*, the point. Of course, there must be electricity somewhere in the neighbourhood, or there could be no electric potential, but the potential of a point is due to the electrification of all bodies which are sufficiently near to exert any electrical action at the point. Thus, a conductor may be at a high potential while its charge is zero, in consequence of other bodies positively electrified in its neighbourhood, and it may, and it often does, happen that a body is at a high *positive potential*, and is, nevertheless, *negatively* charged. This will happen when its own negative charge is insufficient to neutralise the positive potential due to positively electrified bodies in the neighbourhood.

When work is done by electric force on the unit of (positive) electricity in passing from the earth to any point, work will have to be done *against* the electric forces in bringing the unit of electricity from the point to the earth, and the potential of the point (like the level of points below Trinity high-water mark) is reckoned as negative.

When a positively electrified body tends to go from A to B a negatively electrified body will tend to go from B to A, so that, while positively electrified bodies tend to go from places of high to places of low potential, negatively electrified bodies tend to go in the opposite direction.

It is convenient to employ the term *electric field* for any portion of space in which electric forces act.

If a body which is a non-conductor (or insulator) be placed in an electric field, so that some points of the body are at places where the potential is higher than at other points (positive), electricity will tend to pass from the places of higher to those of lower potential, and this being resisted by the insulator stresses will be exerted on the substance of the insulator itself, which will thus be thrown into a state of strain. Thus, any non-conductor, or dielectric, placed in an electric field will experience a state of strain, resisted by the elasticity of the substance, and it is to this state of elastic strain of the dielectric that the *energy* of an electrified system is due. Sometimes the electric stresses exceed the elastic limits of the substance, and discharge takes place, which may be of a disruptive character, and cause the fracture of the dielectric.

If a conductor be placed in an electric field, positive electricity will flow from places of high, to places of low potential, causing the latter to become electrified positively, and therefore raising their potential, while the former become negatively electrified with a consequent lowering of potential. This action will go on until the potential at every point of the conductor is the same, and the distribution of potential throughout the field, as well as in the conductor itself, will, in general, be changed. This action is known as electric *induction*.

If a body be charged with positive electricity, and there be no other charged body in the neighbourhood, the body will thereby be raised to a positive potential, depending on the size and shape of the body, and the amount and distribution of its charge; for a unit of positive electricity in the neighbourhood of the body will be repelled by it, and work will therefore be done upon it as it goes away to the earth.

Similarly, a body charged with negative electricity and removed from the influence of all other electrified bodies will have a negative potential, for there will be a tendency for positive electricity to come from the earth to the body in virtue of the attraction of its negative charge.

But when a number of bodies are near together some charged positively and some negatively, the potential of any one of them will not depend on its own charge only, but in part on the charges of all the others, and thus it may happen, as indicated above, that a body with a negative charge may have a positive potential, and a body with a positive charge may have a negative potential.

Any conductor in communication with the earth must be at potential zero if there is electric equilibrium; for, if its potential were above that of the earth, electricity would flow from the conductor to the earth until equality of potential was produced, while electricity would flow in the opposite direction if the potential of the conductor were below that of the earth.

Thus, a conductor in communication with the earth, and placed near to a positively electrified body, will itself be electrified negatively in order that the potential due to its own negative charge may neutralise the positive potential due to the charge upon the positively electrified body, and thus reduce the potential of the conductor to zero. Similarly, a conductor in communication with the earth, and placed near a negatively electrified body, will itself be electrified positively.

In connection with every electrified surface a series of *equipotential* (or level) surfaces may be drawn such that the work done on the unit of electricity in passing from any point in one surface to any point in the next in order is equal to one *erg*. Such a set of surfaces would be analogous to the set of level surfaces described above, and, as in the case of

Digitized by Google

gravitation, the *electric intensity* at any point will be inversely proportional to the perpendicular distance between successive equipotential surfaces in the neighbourhood of the point.

DEF.—The electric intensity at any point is the force which would act on the unit of electricity placed at that point.

Electric intensity is frequently called electromotive force *at* a point. Maxwell called it electric intensity in analogy with magnetic *intensity* and the *intensity* of gravitation. Instruments intended to *detect* differences of potential are called *electroscopes*. Instruments designed for the *measurement* of differences of potential are called *electrometers*.

It should be borne in mind that electroscopes and electrometers do not serve primarily to detect or measure *charges* of electricity, but simply the difference between the *potentials* of two points connected with each instrument, and called its electrodes, and hence of conductors in communication with the electrodes.

The gold-leaf electroscope consists essentially of two gold leaves suspended from a brass plate or knob by means of a brass rod, and protected from currents of air by a bell glass, through the neck of which the brass rod passes. The gold leaves should be surrounded by a wire-gauge cage placed within the bell jar, and having a wire attached to it which passes out through the stand of the instrument. The brass plate or knob then forms one electrode, and the wire attached to the gauge cylinder the other. If no gauge cylinder is employed, the walls and other objects in the room take its place.

ON LEADS FOR INCANDESCENCE LAMPS.

BY GISBERT KAPP.

In lighting by incandescence lamps, the resistance of leads becomes the more important the greater the number of parallel circuits feeding the lamps. To minimise the influence of lead resistance, it would be advantageous to place as much as possible the lamps in series, but to do that would be to encounter two great difficulties. In the first place, that of great complication in the arrangement of wires, and consequent necessity for the employment of highly-skilled labour, and, in the second place, that of making each lamp independent of all the rest. To make the light really serviceable for household and many industrial purposes, each lamp should be so arranged that it can be independently switched on or off, and if it be placed in series with one or more other lamps, this can only be done by the wasteful and complicated device of inserted resistances. By far the simplest, safest, and cheapest plan is, therefore, not to put too many incandescence lamps in series, but to work them as much as possible in parallel circuits bridging the two main leads. The number of lamps in each parallel will be determined by the unit of light desired. If, for instance, it were found convenient to have a unit of 60 candles, this could be made up of three 20 candle-power lamps placed in series, and then all the three lamps would be lighted or extinguished simultaneously. In most cases it will, however, be found convenient to have a unit small enough to be represented by one lamp, and in this case the difference of potential between the two main leads will have to be about equal to the electromotive force required to work one single lamp. It has hitherto not been found possible to construct reliable lamps of very high resistance and moderate candle-power, and 100 to 110 volts may at present be considered as the limit of electromotive force necessary to work small incandescence lamps.

The natural consequence of such a low E.M.F. is that the resistance of the leads ought to be as low as possible, because a high resistance would not only involve considerable loss of electric energy uselessly transformed into heat, but would also cause a difference of intensity of light according to the distance between lamps and electromotor. Let P_1 denote the potential at the positive terminal of the electromotor, this potential being expressed in units of any convenient absolute measure; P_2 the potential at the far end of positive lead, P_3 that at the far end of negative or return lead, and P_4 that at the negative terminal of the electromotor. In order that the current may flow in the assumed direction, P_1 must be greater than P_2, and $P_3 > P_4$. Therefore,

$$P_1 - P_4 > P_2 - P_3.$$

$E_1 = P_1 - P_4$ is the difference of potential or the electromotive force at the beginning of the leads; $E_2 = P_2 - P_3$ is the electromotive force at the end of the leads.

$$E_1 > E_2.$$

Let E be the electromotive force at any intermediate point, then

$$E_1 > E > E_2.$$

From this it will be seen that the brilliancy of the lamps (supposed all to be of equal resistance) diminishes as their distance from the electromotor increases.

To find the measure in which this takes place, we would require to know for each particular case the way in which the lamps are distributed along the main leads, and as there may be an infinite variety in the arrangement and grouping of lamps, it is impossible to treat the question in all its generalities. We will, therefore, confine ourselves to one special case, and select that of all the lamps being evenly distributed along the main leads. For practical purposes it is quite sufficient to investigate this case only, as it is the one mostly met with, and as it will be found easy to apply, with a little discrimination, the results obtained also to other and more irregular arrangements.

Let l denote the length of each main lead, and n the number of branch leads containing the lamps and bridging across the main leads.

The distance between two parallels is, therefore, $\frac{l}{n}$.

Let r be the resistance of each parallel, and g the resistance of each main lead between two parallels. We assume r to be constant for all the parallels. This is not absolutely correct, but sufficiently so for practical purposes; for it must be borne in mind that, although the lamp resistance depends to a certain extent upon the current passing the lamp, yet the variation in current which may be permitted is so exceedingly small that the corresponding variation in resistance can be altogether neglected.

To make the case amenable to mathematical treatment, we will further assume that the current, instead of being taken off at n fixed points, is permitted to leak gradually across the whole length of the mains. This leakage, however, must be considered to take place in such a measure that along the unit length of $\frac{l}{n}$ an aggregate amount of current just sufficient to feed one parallel is taken off. Let E be the difference of potential between the two mains at a point the distance of which from the electromotor be x, and let C be the current passing along the main leads at that point. To an increase dx of the distance corresponds a decrease dE in electromotive force, and a decrease dC of current—

$$-dE = 2gC\,dx,$$

$$-dC = \frac{E\,dx}{r},$$

$$\frac{dE}{dC} = \frac{2gr\,C}{E},$$

$$E\,dE - 2gr\,C\,dC = 0,$$

$$\frac{E^2}{2} - gr\,C^2 = K,$$

where K, the constant of integration, can be determined by applying the formula to the point $x = o$, that is, the beginning of the leads, in which point,

$$E = E_1, \qquad C = C_1.$$

Inserting the value thus obtained for K, we find

$$E_1^2 - E^2 = 2gr(C_1^2 - C^2). \quad . \quad . \quad (1.)$$

This equation gives the relation existing between electro-

Digitized by Google

motive force at any point of main leads and current passing that point; but it does not say in what manner the position of this point influences either.

It was shown above that the electromotive force between the main leads, and consequently also the brilliancy of lamps, diminishes steadily towards the end of leads, where it is a minimum. For practical purposes we need, therefore, not trouble about intermediate points, as long as we find that the last parallel gets sufficient current. Let C_2 be the current through the last unit of main leads, and therefore, also, through the last parallel, then

$$\frac{E_2}{r} = C_2.$$

This equation combined with 1 gives

$$E_2 = \frac{1}{\sqrt{1 - \frac{2g}{r}}} \sqrt{E_1^2 - 2gr C_1^2}.$$

Let $R = \frac{r}{n}$ be the total resistance of all the n parallels, and $R_0 = 2ng$ the total resistance of main leads. It will be seen that $\frac{2g}{r} = \frac{1}{n^2}\frac{R_0}{R}$ is an exceedingly small quantity, which can be neglected. We have, therefore,

$$E_2 = \sqrt{E_1^2 - R R_0 C_1^2}. \quad . \quad . \quad . \quad . \quad (2.)$$

This formula is almost rigorously correct.

A less correct but still insufficiently approximate value for E_2 can be obtained by developing the square root into a series and neglecting the third and subsequent members, which are very small quantities. Approximately we can put $E_1 = R C_1$, and obtain

$$E_2 = E_1 - \tfrac{1}{2} R_0 C_1. \quad . \quad . \quad . \quad . \quad . \quad (3.)$$

$R_0 C_1$ is the electromotive force necessary to drive the total current right along the main leads, supposing their far ends to be joined up and the branch leads to be all cut out. We have now the following easily-remembered rule. *The loss of electromotive force between the first and last parallel is equal to one-half the electromotive force which would be necessary to drive the total current right round the main leads if their far ends were joined up.*

This rule is, however, only approximately correct, and the approximation will be the nearer the smaller the resistance of main leads in comparison to that of the lamps. It would be quite correct if each parallel would get the same current; for in that case we have—

$$-dC = \frac{C_1}{n} dx,$$

$$-dE = 2gC\,dx,$$

$$\frac{dE}{dC} = \frac{n}{C_1} 2gC,$$

$$E = \frac{n}{C_1} gC^2 + C,$$

where K, the constant of integration, is found by applying the formula to the first parallel, where $E = E_1$ and $C = C_1$.

$$E_1 - E = n g C_1 \left(1 - \left(\frac{C}{C_1}\right)^2\right).$$

For the far end of the circuit, $E = E_2$, and $C = 0$,

$$E_2 = E_1 - n g C_1,$$

$$E_2 = E_1 - \frac{1}{2} R_0 C_1.$$

This is the same formula as obtained above. It is only correct if all the parallels receive the same current, as might be the case if they were clustered together about the middle of main leads. In this case the total current would be

$$C_1 = \frac{E_1}{\frac{R_0}{2} + R} \quad . \quad . \quad . \quad . \quad . \quad (4.)$$

In the case of the lamps being evenly divided along the leads, this value for the total current must be regarded as a first approximation to the real value. Similarly, we find as a first approximation for E_2 the value

$$E_2 = E_1 \frac{R}{\frac{R_0}{2} + R} \quad . \quad . \quad . \quad . \quad . \quad (5.)$$

This may now be used for finding a second and nearer approximation for the total current by the formula

$$C_1 = \frac{E_1 + E_2}{2R} \quad . \quad . \quad . \quad . \quad . \quad (6.)$$

Inserting this into formula 2, we get an almost mathematically correct value for E_2. Example:—

Sixty lamps, each of sixty ohms resistance, when hot are to be worked in single parallels, between two leads of $R_0 = 0{\cdot}1$ ohm total resistance.

Electromotive force necessary to bring the lamps to incandescence be 88 volts. Lamps evenly distributed. Neglecting the trifling resistance of short branch leads, we have $R = 1{\cdot}00$.

We assume $E_1 = 90$ volts.

By using formulæ 5 and 4 we have as a first approximation:—

$$E_2 = 85{\cdot}71,$$
$$C_1 = 85{\cdot}71.$$

Inserting this into 4 and 3 we find as a second approximation:—

$$E_2 = 85{\cdot}61,$$
$$C_1 = 87{\cdot}85.$$

The latter value inserted into 2 gives the almost mathetically correct value for the electromotive force at the end of main leads:—

$$E_2 = 85{\cdot}65.$$

Thus our 88 volt lamps would get 90 volts close to the electromotor, and only 85·65 volts at the greatest distance from it. The difference of 4·35 volts is almost too great to be compensated by the inequalities of the lamps, and slightly heavier main leads than those described above ought to be used in this case.

PHYSICAL SOCIETY, NOVEMBER 25.

Professor CLIFTON, President, in the Chair.

A paper by Mr. William Ackroyd on "Rainbows Produced by Light Reflected Before Entering the Raindrops" was read by the SECRETARY. The author investigated mathematically the rare phenomenon of three bows, and inferred that it would generally take place about sunrise or sunset.—Mr. LECKY thought the effect had a simple explanation. It might be said to be due to two suns, one (reflected) appearing to be below the horizon.

Mr. SHELFORD BIDWELL gave an account of some experiments he had made to test the theory of Dr. James Moser that the action of a selenium cell under light was due to the heat rays making a closer microphonic contact between the selenium and the metal electrodes by expanding the material. He submitted selenium cells to dark heat rays, and found their resistance to *rise*. Under light rays, however, their resistance fell. He therefore concluded that Dr. Moser's theory was erroneous, and that the fall in resistance due to the light rays is the differential result of the rise due to heat and the fall due to light. He also explained the "fatigue" of a selenium cell by use, as caused by its increase of temperature. When the cell cooled again the fatigue disappeared.

Dr. JAMES MOSER then read a paper on a "General Method of Strengthening Telephone Currents." This consists in forming a primary circuit of the telephone transmitter, or derived circuit, a set of induction bobbins in derived circuit, and a charged secondary battery, the whole circuit having a very low resistance. Each primary bobbin has a secondary wound over it, and these secondaries are connected "in quantity" to the telephone line, which has at its remote end a set of telephones in derived circuit to the earth or return wire. In this way one line more serves to supply a large number of separate telephones, a hundred being employed by Dr. Moser to transmit music from the Hippodrome in Paris to the Place Vendôme. The system is applicable to long lines, and the induction noises are reduced by subdivision among the separate telephones.

CORRESPONDENCE.

SECONDARY BATTERIES.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I notice with much interest the letter from Mr. Cowley in your issue of December 2nd. It is certainly surprising that his friend should have found so much difficulty in purchasing accumulators, and I shall be pleased indeed to see any reason for the company's reluctance to sell.

It is to be hoped that in any future references to accumulators the information given will be more definite than has been usual in time past. For instance, in *The Electrician* of November 25th, there is a letter, signed "Ayrton and Perry," from which it may be inferred that, while travelling in a hansom cab, railway carriages, &c., they have kept three incandescent lamps burning. But, although the weight of the accumulator employed is given, no mention is made as to the duration and amount of lighting.

There is another matter which demands attention. In *The Electrician* for October 28th, Mr. Bosanquet says that some Faure cells, made by himself, underwent changes when left charged for any time. The acid was rapidly abstracted from the liquid, considerable quantities of sulphate of lead were formed, and this considerably impairs the efficiency of the battery.

We are naturally impelled to ask what is the cause of this. A secondary battery has been likened to a Leyden jar, but the leakage above referred to must necessarily be connected with some chemical changes which go on in this form of secondary battery. Now, so far as the chemistry is concerned, little or nothing was known until the researches of Gladstone and Tribe were published, and these throw a considerable light on the loss referred to by Mr. Bosanquet.

The difficulty of obtaining cells from the public companies, and the statements of Mr. Bosanquet, combine with many isolated facts to raise doubts as to the retaining power of accumulators. There is no doubt that the problems these batteries present are of a special order, and require special technical knowledge for their solution. But there is promise that the difficulties will be removed in the fact that qualified men like Mr. Bosanquet and Mr. Tribe are devoting their energies to improvements, and I trust that before long we may have a reliable storage battery.—Yours, &c., W. H.

Dec. 4, 1882.

A TELEGRAPH LINE WITHOUT INSULATORS, &c.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I want to know what has become of James V. Fry. On October 28th you published a letter from him announcing that he had discovered two astounding facts, viz., how to construct a telegraph line 200 miles long without insulators, and how to make a galvanic battery out of pure rain water. On November 11th a subscriber, signing himself "M. Practical," wrote, recognising the great importance of these inventions, and asking for some particulars of them. These James V. Fry has hitherto disdained to give. Why? He says that he actually gave successful effect to both inventions in Japan. Either this is true or the reverse. If the first, let him say how he did it. If the second, James V. Fry's—if there is really such a person—silence is not difficult to understand.—Yours, &c., M. (PRACTICAL)^2.

London, Dec. 4, 1882.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I am astonished that Mr. James V. Fry has not responded to the invitation of "M. Practical" in your number of Nov. 11, to explain *how* he worked 200 miles of wire without insulators, and *how* he made a voltaic battery with pure rain water.

He says he did these things, but carefully omits to state *how*. If some satisfactory explanation is not soon forthcoming, I, for one, shall know what to think of Mr. James V. Fry.—Yours, &c., INQUISITIVE.

Glasgow, Dec. 4, 1882.

RESISTANCE BOXES.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: The letter bearing signature "Student" in your issue of November 11 has received our due attention. We have carefully examined patent No. 212 of the year 1852, from which he has quoted, and have also taken opinion thereon (copy of which we shall be happy to forward to any one on application). We find the words, "iron wire of different thicknesses embedded in pipe-clay, alumen, or asbestos," as quoted by "Student" to be correct; but we would impress upon "Student" that he has quoted the words without the context. In the drawings, and by *necessity of construction*, the wires in this resistance are only *partially* embedded, showing clearly that Messrs. Slater and Watson were considering the matter of insulation and rigidity only, absolutely without reference to safety from fire or to diminution of the size of wire used for resistance purposes. Such a box the public are, of course, at liberty to make, though any system of embedding, in the sense and for the purpose of patent No. 5,743, of 1881, will be considered as an infringement of that patent.—Yours, &c., G. PFANNKUCHE

(for Pfannkuche and Dunston).

25, Charlotte-street, Fitzroy-square, W.C.,
December 6th, 1882.

OHM'S LAW.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: If "J. A. S." would regard C (which he calls "the available force") as the quantity of electricity that flows through any section of a circuit in a unit of time, say a second, I think it would assist him.

When two bodies, unequally electrified, are insulated and connected by means of a conductor having a certain resistance, a current of electricity will flow from the body having the greater potential to the other, and should we employ a conductor having twice the resistance of the previous one, Ohm's law shows us that the quantity of electricity flowing through any section of the former in a second is twice as great as that flowing through any section of the latter in the same time.—Yours, &c., J. R. HARVEY.

20, Kent-road, Ford, Devonport,
December 5, 1882.

BOOKS ON ELECTRIC LIGHTING, LECTURES, &c.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Could any of your readers recommend me a good practical book on electric lighting, including some of the more recent inventions. I should also be glad to know of any elementary lectures, in London, on mechanics and engineering, suited for an electrical engineer.—Yours, &c.,

STUDENT.

LECLANCHÉ BATTERIES, AGGLOMERATE FORM.

TO THE EDITOR OF THE ELECTRICIAN.

A correspondent writes:—"What length of time will the agglomerate plates of above last? Is there any test you can put to them to discover when nearly worked out other than the E.M.F. decreasing? Having just adopted them, shall be glad of any hints on their management."

[Our correspondent cannot do better than consult the India Rubber, Gutta Percha, and Telegraph Works Company, of Silvertown, E., for the information he requires.—ED. *E.*]

The Board of Trade and Electric Lighting	84		

THE BOARD OF TRADE AND ELECTRIC LIGHTING.

The deputation which waited upon the Secretary of the Board of Trade on Tuesday last with reference to the working of the Electric Lighting Act was a fitting commentary upon that premature and ill-considered measure. We have predicted all along that its provisions, so far from promoting the permanent interests of electric lighting, would provoke the hostility of the very people whom its friends desire most to conciliate; and this is actually what is occurring. On two or three quite distinct grounds the Bill was calculated to arouse opposition. It conflicts with those most highly cherished views of local self-government which, whether exaggerated or not, are facts the Bill seems to have wantonly disregarded. Practically, the whole power of the local authorities in relation to this particular business has been transferred by a side wind of legislation to the Board of Trade—really to its secretary for the time being. Further, it becomes plainer and plainer every day, although the statement has been denied many times, that the corporations are compelled, or may be compelled, to incur considerable sums on "experimental lighting," whether they like it or not. Now, much as the genuine advocates of electric lighting desire to convince the local magnates of its many advantages, they never wished their arguments to be backed by force. Indeed, force was just the very element most likely to be met by force, and if it comes to a question of fighting there can be no manner of doubt that even Mr. Chamberlain is no match for the united opposition of the local authorities.

There are other defects in the Bill; but we have dealt with them pretty fully in former articles. The two just referred to, however, were the main subject of remonstrance at the Board of Trade on Tuesday by deputations from the principal towns of England and Scotland. Their complaint is the more deserving of notice because it does not come from opponents of electric lighting. The deputation represented only those corporations which were desirous of dealing with the matter themselves—that is to say, they wanted powers to introduce the light under the control of their respective local boards, but with the liberty to exercise it when and how they might deem best. Nominally the deputation came to urge the desirability of making the use of the electric light permissive and not obligatory. But what they really meant was that their adoption of it should be permissive, whilst the exclusion of private undertakings should be obligatory. This might result in the corporations securing licenses for themselves which they never intended to use, except as a means of preventing the invasion of outsiders. It was against such action as this that, according to Mr. Chamberlain, Parliament was anxious to protect the would-be consumer. In reality we know very well that what Parliament was hurried into doing was to lend a helping hand to the speculating public, and if possible avert the financial catastrophe which was then threatening it. Still, there was the contingency that the local authorities might act the dog-in-the-manger, neither adopting the new illuminant nor letting any one else introduce it. At first sight such a course would appear most unreasonable; but everything turns upon the question of urgency. The Bill set out with the assumption that the general adoption of the electric light was possible and instantly needed. We sincerely wish it had been so. But the assumption was too transparent, as we have said from the first, to stand the test of calm reasoning; and, accordingly, we see the corporations asking for delay, for time to consider, to weigh the relative merits of the competing systems, and to adjust their local arrangements so that the introduction of a new system of lighting may not inflict upon the ratepayers a heavy pecuniary penalty.

Putting the most sinister construction on the representations of the various corporations who ask for powers, but have no present intention of using them, the case is one for compromise, not for compulsion. If this Bill had been for the promotion, say, of glass paving-stones or paper drain-pipes, its absurdity would have been evident from the first. Not that the use of glass and paper for purposes of that kind is absurd, but to legislate for their introduction into any and every parish would be. It would be worse than absurd, it would be a blunder, and it would fail. This is our complaint against the Electric Lighting Bill: We think it will fail to accomplish what the best friends of electric lighting are anxious should be accomplished, and what would have come

Digitized by Google

about, perhaps, much better and quicker without any Bill at all.

We are afraid the deputation did not carry away much comfort from what the Secretary of the Board of Trade had to tell them. He mildly reproved them for not having foreseen what neither he himself nor the parliamentary committees appear to have foreseen; and likewise for not having stated their objections to clauses which they had no opportunity of seeing till the Bill was passed. He tried to impress them with the profound anxiety felt by Parliament for the promotion of "electrical sciences," and the pain it would suffer if any corporations or local authorities hindered or delayed the movement it had so much at heart. This was most touching, and in pathos was hardly surpassed by his reference to the "claims, duties, and privileges of municipal government." No man in England could have a higher opinion of them than himself. He believed that it was for the general good that everything should be done to add to the authority, the influence, and dignity of their local life. Perhaps the deputation were expected to infer that their immediate adoption of the electric light would greatly contribute to "the dignity of their local life;" but as regards their authority, he did not deny—he could not conceal from himself—he even admitted, that the Act of Parliament had placed very great discretion in the Board of Trade. Such of the deputation as have implicit faith in the great discretion of the Board may rest content on this; but they must not talk any more about the discretion of municipal governments, much less of their rights, for in this matter they have ceased to possess any.

The transfer of the rights of local authorities to the Board of Trade may, as we have before stated, give rise to much dissatisfaction as well as inconvenience. The present secretary told the deputation that he did not see how the Board of Trade could make any distinction between corporations and companies in reference to provisional orders. Neither do we, and perhaps it is right there should be no distinction in a matter of detail. But when it is a matter of distinguishing between one applicant company and another, on what principle, we should like to know, is the Board to make choice? Not by tender, not by local preference, nor, it may be hoped, by reference to quotations on the Stock Exchange. Perhaps this new-born zeal for science which Parliament has placed in the discreet lap of the Secretary of the Board of Trade may portend that every competing system seeking a provisional order will be tested scientifically before the order is granted. If that were the case, we should have no apprehensions about the result; but to transfer the responsibilities of the test to the local authorities, and to make them pay for the experiment, is almost certain to court determined opposition and ensure ultimate failure. One good result we may hope from this deputation, and from the very explicit answer which the Leeds authorities have received from the Board of Trade touching its interpretation of the Act, namely, that the competing companies alone will be left to fight the battle of electric lighting, without hindrance or patronage from local authority or Board of Trade.

STORAGE BATTERIES.—In reply to Mr. Cowley, several managers of companies have written to us stating that they are prepared to take orders and deliver storage batteries. We cannot undertake to advertise these companies' wares—that, we imagine, is a part of their business. We have performed our share of the work when we have shown that the want exists.

STUDENTS' COLUMNS.

CITY AND GUILDS EXAMINATIONS.

[*These answers are intended to guide, to give information and references, to put the student in the way of getting information, and* NOT *to give the exact answers that should be written in an examination.*]

The solutions in this number are contributed by E. C. RIMINGTON, Esq. (School of Electrical Engineering), 12, Princes-street, Regent-street.

11. What is the principle of a photometer? What form of photometer is most suitable for use with strong electric lights? What sort of results are obtained for the illuminating power of an electric light when it is examined through green and through red glass respectively? How does the intensity vary for beams at different angles in the same vertical plane for arc lights, and for incandescent lights—first, when a continuous current; second, when a reverse current is employed?

Ans. The principle of the photometer is that light varies inversely as the square of the distance; thus, if two lights give the shadows of a vertical bar on a white sheet of paper of the same intensities, and the distance of one is 40ft. and of the other 4ft. from the paper, the farther light will be 100 times the candle-power of the nearer.

The form of photometer best suited for measuring arc lights is the dispersion photometer of Messrs. Ayrton and Perry, in which the rays coming from the stronger light are passed through a concave lens (generally having a focus of 4in.), and thus rendered divergent. This method allows of the stronger light being placed much nearer the photometer than it otherwise could be.

When the rays of light from an electric arc lamp and a standard candle are passed through a sheet of green glass, the illuminating power of the lamp compared with the standard candle is greater than under normal conditions, when through red glass less.

The reason of this is that the standard candle contains more red and yellow rays than the arc light, while the arc light is far richer in violet rays than the candle. Now, when the two lights are passed through green glass, the blue in the glass absorbs a great part of the red and yellow rays, but allows the violet rays to pass with very slight loss. In the case of the red glass, the red and yellow rays are allowed to pass, while the blue and violet are absorbed.

In arc lamps, the greater the angle that the beam of light makes with the horizon when the lamp is suspended vertically the greater intensity it possesses. In direct current arc lamps, where the top carbon is the positive, the intensity is greater for a beam of light at any angle below the horizontal line passing through the arc than for the same angle above it. This is due to the crater that forms in the positive carbon acting like a concave reflector, and condensing the light downwards. In arc lamps worked by alternating currents the intensity is the same for the same angle whether above or below the horizon.

12. Describe, with sketches, the construction and action of any instrument you are acquainted with for measuring strong currents. What are the currents in amperes used respectively in the various systems of electric lighting?

Ans. The two instruments principally employed at the present time for measuring strong currents such as are employed in electric lighting are Ayrton and Perry's ammeter and Siemens's dynamometer. The former is simply a modified galvanometer, made exceedingly dead beat by the use of a very light aluminium pointer, and by making the needle move in a strong magnetic field. The coil surrounding the needle consists of ten strands, each of exactly the same resistance. By means of a commutator these ten strands can be joined either in series or in multiple arc. Thus the sensibility of the instrument can be increased ten times, either for the purpose of calibration, or for measuring small currents under three or four amperes. Siemens's dynamometer is constructed on the well-known principle that currents flowing in the same direction attract, and in opposite directions repel one another. It consists of two coils of wire, one fixed, the other suspended by a fibre and free to move. The movable coil generally consists of a very few turns of thick wire, and is mounted in mercury contact cups, so that the current enters at one terminal of the instrument, flows through the fixed coil, then through the movable coil, and out at the other ter-

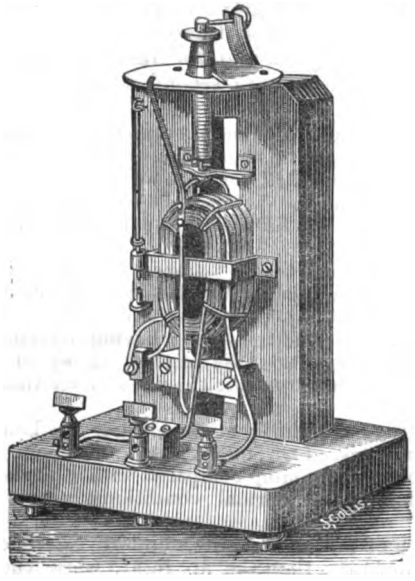
Digitized by Google

minal. A pointer is fixed to the movable coil, and vibrates between two stops on a dial at the top of the instrument; the top of this coil is attached to a fine brass wire torsion spring, the other end of which is fixed to a milled head, provided with a pointer, which can be turned round the dial. The dial is divided into 360 degrees.

When a current is sent through this dynamometer, the movable coil tends to set itself parallel with the fixed one, its pointer, therefore, moves against one of the stops, the milled head is now turned round till the torsion of the spring counteracts the attraction of the coils, the number of degrees registered by its pointer are then read off,

$$\text{when current} = \sqrt{\text{angle of torsion}} \times k,$$

where k is a constant found by calibrating the instrument. One great advantage of this form of dynamometer is that it can be employed with alternating currents. The currents employed to work arc lamps are generally from 10 to 20 amperes, while for



Siemens' Dynamometer.

the incandescent system they vary from 1 ampere, or less, to over 4.

13. Why does a spark occur in breaking the circuit of an electric lamp? Give a sketch of a switch so constructed that the spark on opening the circuit is very small. Why does no spark occur on closing the circuit?

Ans. When the circuit of an electric lamp is broken, the metal at the point where the interruption is made becomes vaporised, and a short arc is momentarily established across the space between the two portions of metal by reason of the conducting power of this vapour.

To prevent this some switches are constructed so as to simultaneously break contact at more points than one, thus reducing the sparking at each point to a minimum. On closing a circuit the reason no spark occurs is that there is no metallic vapour to conduct a current across the gap between the two pieces of metal. But even then, if we bring two wires having a very great difference of potential between them exceedingly near one another, a disruptive discharge occurs through the air, and an arc is established between them.

14. Explain in detail how electricity can be used for transmitting power, and how by its employment sources of power at present wasted may be practically utilised?

Ans. The motive power at command is employed to turn a dynamo, the current from which is conducted by wires to the place where the power is required. Here it is passed through a dynamo or electro-motor, which is thus made to revolve, and can be employed to perform the required work. In thus transmitting work the greatest electrical resistance should be where the power is to be utilised, *i.e.*, in the amature and field magnets of the electro-motor; consequently, the dynamo at the source of power must be of high E.M.F., and fairly low resistance, therefore it must be driven at a very high speed. The current of a river, or a waterfall, may be employed to turn a wheel, which is connected by means of gearing or straps with a dynamo. The ebb and flow of the tide might be utilised in the same manner.

15. How can the direction of rotation of a dynamo used as an electro-motor be reversed? Why ought an electro-motor not to be attached to the axle of a tramcar, and drive the wheels directly without the employment of speed reducing gear?

Ans. The only method of reversing the direction of rotation of an ordinary dynamo machine used as an electro-motor is to send the current in the same direction round the armature as when the dynamo was employed to produce a current, but in the reverse direction round the field magnets, or *vice versâ*. This can be done by reversing the connections of the field magnets with the armature.

To work an electro-motor economically it should be driven at a fairly high speed, that is to say, a speed much higher than the rate at which the wheel of a tram car revolves. We are consequently obliged to employ speed-reducing gear.

NOTE ON CHARGING SECONDARY BATTERIES AND ON A DYNAMO OF CONSTANT E.M.F.

BY R. H. M. BOSANQUET, ST. JOHN'S COLLEGE, OXFORD.

I should like to make some remarks on the interesting letter of Messrs. Crawley and Rimington in your number of Dec. 2, with reference to my notes which you reprinted from the *Philosophical Magazine*.

While I have no doubt that the method described by them is practical, it seems to me open to objection; and I still prefer my own method, though it may doubtless be improved, as I shall show.

When I start the machine with the resistance in circuit (I use about 6 ohms, not 5), the resistance ought to be so arranged that the speed of the machine is about the same as it will be when the accumulators are charging, and with the same power applied. The only point then necessary to be observed is to make the time of transfer, during which battery and resistance are in parallel circuit, very short, and to take care that there is plenty of power. It is easy to make the duration of the parallel circuit a second or so, and it may be made much less by a simple contrivance. Under these circumstances, the heavy load of the double circuit has not time to check the speed, and this proceeds unaltered. I find no difficulty in doing this by hand, making the contacts of the battery by a movement of the commutator with one hand, and releasing the resistance with the other. But it would be easy to arrange an overlapping contact for the resistance on the commutator handle, so that this should be done automatically by the one movement. I have often thought of doing this, but have never carried it out, as my present system is sufficient in practice. I did not describe my commutator, nor enter into minute particulars, as I wished to be concise, but I may say now that the commutator has three handles. Two control the parallel circuits, to right when machine is straight, to left when reversed; and the third joins them up, to right in parallel circuit, to left in series. The final contact is made with the third handle, and so with one movement.

There are one or two points requiring notice in the arrangement of Messrs. Crawley and Rimington. One is, that when cells are added they are short circuited during the overlapping contact. This does not matter if one remembers it and moves the handle quickly, otherwise mischief may ensue. I have burned my fingers before now in carrying out a plan of similar kind for changing the arrangements while charging.

The drop from the resistance of 5 ohms to that of the first 5 cells is a severe one; there is much more shock in this than with anything in my system. In adding 5 cells at a time there is a great risk of reversal when the margin of power is narrow.

It is not my experience that cells are more difficult to charge after an interruption. When the cells are in an unused condition I find the acid generally very completely absorbed, and the resistance high. I avoid continual additions of acid as much as possible, and at first it is sometimes difficult to get the current through. After a few minutes there is a great improvement, unless the cells have been idle for weeks, in which case they often give trouble for several

Digitized by Google

days. This more than counterbalances the variation in the E.M.F.

While writing I wish to mention another subject, which is of great interest.

Early this year, in conversation with Mr. Swan, I observed that shunt circuit machines could not be used with common arc lamps (*e.g.*, Serrin), since the contact of the carbons would divert all the current from the shunt and stop the action. Mr. Swan suggested the employment of a main circuit as well to get over this, and pointed out that it was possible that such a combination might give rise to an E.M.F. which would be constant under varying external resistance. Lately I obtained Mr. Swan's permission to make use of the suggestion, and have worked the matter out. Since I did this I have seen (*Engineering*, Dec. 1, p. 530), a general description of a dynamo by Paget Higgs, in which I recognise the principle I have worked out. I believe also that machines are being made on this principle by Mr. Crompton. As I think that the investigation is of interest, I subjoin it. I have applied the numbers to the magnets of my Gramme machine, so that I may be treating of an actual case.

I suppose the shunt to be taken straight from the armature brushes.

Resistances.

R armature, r external, and main magnet coils, ρ shunt coils.

Number of Coils.

n main magnet coils, ν shunt coils.

E.M.F.

E total E.M.F., e between armature terminals.

$$\text{So that } e = \frac{r}{R + r} E$$

Intensity in axis of solenoid is $\frac{4 \pi n C}{L}$.

The length L is supposed given; then the magnetising force depends on nC, which I shall call coil amperes. In my machine, as it stands, n is 1,000 nearly; and the current is about 20 amperes when the machine is well excited, driving an arc light for instance. Then 20,000 coil amperes are required to excite the iron cores properly. These are to be supplied partly from a main and partly from a shunt circuit, so that

$$n C + \nu \frac{e}{\rho} = 20{,}000 \quad . \quad . \quad . \quad . \quad . \quad \text{(I.)}.$$

Vary the external resistance, denoting the change by an accent; then

$$n C' + \nu \frac{e'}{\rho} = 20{,}000,$$

subtracting $\quad n (C - C') + \nu \frac{e - e}{\rho} = 0;$

and by Ohm's law,

$$n E \left(\frac{1}{R + r} - \frac{1}{R + r'} \right) + \frac{\nu E}{\rho} \left(\frac{r}{R + r} - \frac{r'}{R + r'} \right) = 0,$$

whence $\quad n (r' - r) + \frac{\nu}{\rho} R (r - r') = 0,$

and $\quad \frac{n}{R} = \frac{\nu}{\rho} \quad . \quad . \quad . \quad . \quad . \quad . \quad \text{(II.)}.$

If this relation is satisfied, the number of coil amperes remains at 20,000, if it once has that value, independently of the external resistance; the excitation of the magnets is constant, and with constant speed the E.M.F. must be constant.

The number $\frac{\nu}{\rho}$ represents the number of coils of the shunt wire which go to 1 ohm resistance.

This is determined, if we assign the electromotive force to be used, and the coil amperes required. Putting the external resistance great, or not joining up the main circuit, we have from the first equation, leaving out n C,

$$\nu \frac{e}{\rho} = 20{,}000.$$

If we wish to work with E = 100—in this case e between the terminals = 100 also, and $\frac{\nu}{\rho} = 200$—the wire must be such that 200 coils have a resistance of 1 ohm on the average.

Then, from Equation II., $\frac{n}{R} = 200$ also. The resistance of my armature may be taken at ·5 ohm roughly; then $n = 100$, and 100 coils of the main circuit must pass round the magnets.

The length of shunt wire used determines the economy of the excitation of the shunt circuit. Suppose we used 1,000 coils; resistance, by above, = 5 ohms; current = 20 amperes; $e = 100$; volt amperes = 2,000, or between 2 and 3 h.-p. in exciting the shunt magnets. Suppose we use 10,000 coils; resistance = 50 ohms; $e = 100$; current = 2 amperes; volt amperes = 200, or about quarter of a h.-p.

In fact the number of volt amperes is,

$$\frac{e^2}{\rho} = e^2 \times \frac{200}{\nu},$$

and the horse-power is $\frac{e^2 \cdot 200}{746 \nu}$ for this wire.

It is easy to show by examples that the condition of constancy of excitation is satisfied.

Suppose R + r = 1 ohm, then R = . 5, r = . 5, C = 100^a, $e = \frac{1}{2} \cdot E = 50^\nu$ Then

$$n C + \frac{\nu}{\rho} e = 100 \times 100 + 200 \times 50 = 20{,}000$$

coil amperes, as before. The machine could not well be employed under these circumstances, as the heating of the armature would absorb nearly seven horse-power. Of course it was not constructed for such a purpose. The shunt excitation enables one to use higher resistances in the external circuit, and thus avoid the heating of the main circuit in the machine.

In my machine the average diameter of the coils will be about a foot. I find by calculation that 200 feet to an ohm gives ·12 centimetre for the diameter of a copper wire ·1. By measurement I find this to correspond to No. 18 B.W.G. This wire will carry more than two amperes, and the number of coils might be taken at less than 10,000, if economy of power is not a first object. Five thousand coils will absorb half horse-power when all the excitation is in the shunt. Less length than this would scarcely be admissible.

It only remains to be shown that in a shunt exciting circuit the power expended depends only on the weight of copper wire, when the wire is determined by the equation $\frac{\nu}{\rho} e$ = coil amperes required.

$$\text{Weight} = k \times \text{length} \times \text{section}.$$

$$\text{Resistance} = \kappa \times \frac{\text{length}}{\text{section}}.$$

$$\therefore \text{ weight} \times \text{resistance} = k \kappa (\text{length})^2$$

$$\text{length} = 2 \pi r \nu \ (r = \text{mean radius})$$

$$\therefore \frac{\text{resistance}}{\nu^2} = \frac{k \kappa (2 \pi r)^2}{\text{weight}}.$$

$$\text{Power} = \frac{e^2}{\rho} = \frac{1}{\rho} \left(\frac{\rho}{\nu} \times \text{coil amperes} \right)^2 = \frac{\rho}{\nu^2} (\text{coil amperes})^2;$$

whence, substituting for $\frac{\rho}{\nu^2}$,

$$\text{power} = \frac{k \kappa (2 \pi r \times \text{coil amperes})}{\text{weight}};$$

or the power expended in excitation of the shunt is inversely as the weight of copper, however the E.M.F. may vary, so long as the wire is determined for the existing value of E by the above equation. And there is no use in trying to economise by varying the E.M.F. and wire so long as the shunt coils furnish the chief excitation.

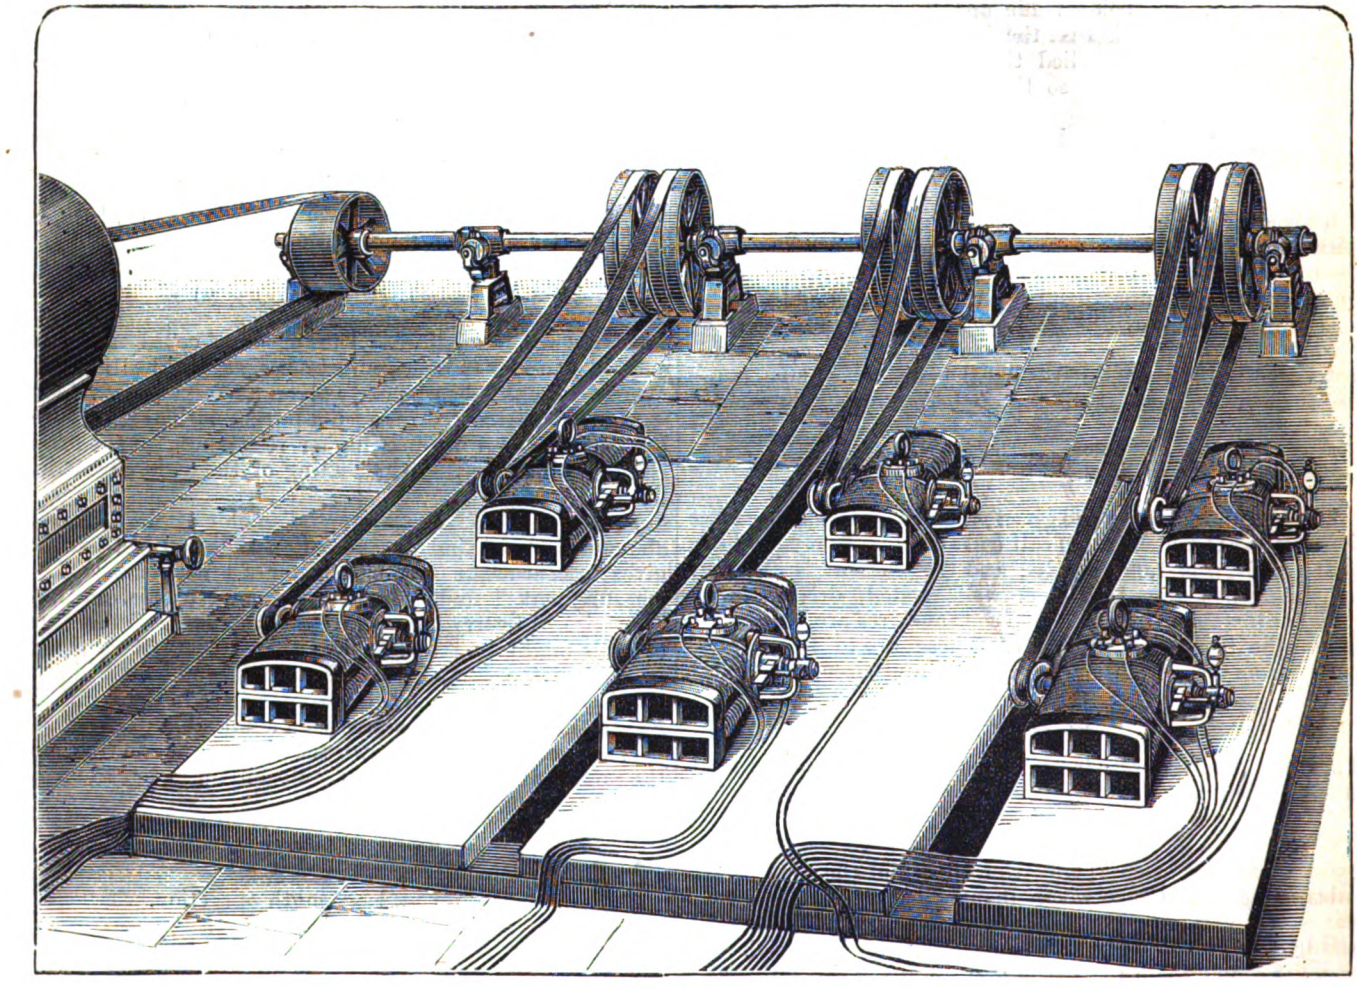
In the event of the machine being used as a motor, it would be necessary to reverse either the shunt or the main coils, as otherwise they would be opposed. The above arrange-

Digitized by Google

ment would have extraordinary advantages when thus applied, the main circuit exciting the magnets at starting, and the shunt circuit after the counter force is set up. The Gramme machine can never answer as a motor without shunt coils, for as soon as the counter E.M.F. is set up the main current is checked, and the excitation of the magnets falls. The shunt circuit is then a necessity.

THE ELECTRIC LIGHT AT THE LAW COURTS.

Herewith we give an illustration of the temporary machine room at the Law Courts. In our next issue we intend to give illustrations of the arrangement of the lamps in the interior of the building, as well as other details of the apparatus. Meanwhile, we may say that in the course of three weeks Messrs. R. E. Crompton and Co. completed the temporary light arrangements sufficiently to exhibit the light on Monday last, the day of the formal ceremony of opening the new Courts by the Queen. Crompton arc lamps are placed in the Great Hall and in the Quadrangle, Swan incandescent lamps in the corridors, staircases, Courts of Appeal, and adjoining Courts. The motor is a Marshall and Sons' engine, the dynamos are of the Bürgin type, as manufactured by Messrs. Crompton and Co. Over four miles of main wires have been laid in the building, and the fittings of most of the Swan lamps are complete and the lamps fixed. The light on Monday was very good indeed. Some of the details of the arrangements at the Law Courts are similar to but on a larger scale than those at Berechurch Hall, and, therefore, instead of illustrating the latter, as mentioned last week, we shall illustrate the former.



Arrangement of Dynamos at the Law Courts.

"IOLANTHE" AT THE SAVOY THEATRE.

Our readers need not fear that we are about to compete with "G. A. S." in the *Illustrated London News*, and to give a graphic description and criticism of the new play. We, like a good many others, have approved of recent plays provided under the management of Mr. D'Oyly Carte, but we approve more, perhaps, his practical appreciation of, and trust in, the electric light. His theatre is lighted by this means, and now he has proceeded further, and has included it among the accessories of personal adornment upon the stage That the electric light lends itself to this end must be admitted, but credit is to be given to the manager who inaugurated the use and the electricians who carried his ideas into effect. Some one signing himself "A. I. C. E." lately made himself and *The Times* ridiculous by writing to that paper of the dangers to be apprehended by this use of the electric light. The old saying, "A little knowledge is a dangerous thing," in this case was justified, and the knowledge "A. I. C. E." possesses amounts apparently to the value of x when x is infinitesimally small.

We give herewith illustrations of the apparatus in use at the Savoy Theatre, but with the remark that improvements have already been made and will probably be introduced in the course of a week or two. These improvements relate more to the weight to be carried than to other details. The apparatus is, we believe, the joint production of the Swan and Siemens Companies, and the carrying out of the arrangements has been in the hands of Mr. W. E. Rogers, who has the charge of the electric lighting arrangements at the Savoy under Messrs. Siemens and Co. It will be remembered that Messrs. Siemens have had the sole management of the electric light at the Savoy since the commencement of its use.

Digitized by Google

The current is supplied at the time required by three small Planté secondary batteries of special construction. These cells are enclosed in gutta percha holders. Externally they appear as in Fig. 1. The hydrogen which escapes during the charging passes through small openings, which can be closed by coned stoppers, effectually avoiding any spilling of the acid. Shoulder straps are attached to the battery as shown, by means of which it can be carried like a knapsack, but as

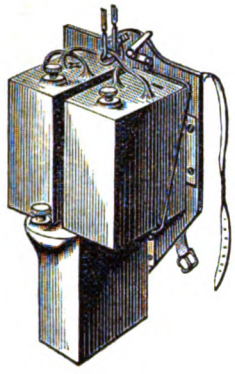


Fig. 1.

an additional security it is provided with a pair of hooks which are fixed into sockets sewn on the dress. The sketch of the lamp-holder, Fig. 2, and its connections almost explains itself. A flexible double wire is used which can be connected with the battery by forks of springy brass wires, supposing the apparatus fixed, and the light required. All that has to be done is to close the switch shown at the top of the battery. The whole

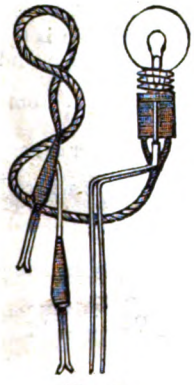

Fig. 2.

apparatus as now used weighs over 4lbs., but the improved apparatus is expected to weigh about 3lbs., perhaps less, no great weight certainly, nor dangerous in any way. It is intended, we believe, to use two cells instead of three, but we have seen a little lamp that can be worked by means of one cell. The lamps at present used give an intensely white light of about six candles. The E.M.F. of the battery is about 5 volts, and the current through the lamps about 1·5 ampere. Any per-

Fig. 3

son conversant with the veriest rudiments of electricity will know from this description, and from these figures, that harm to the fair skins of the wearers is about as likely as that the wearers will visit the North Pole before Christmas. Fig. 3 shows the lamp used. It is full size. We hope that the use of the light at the Savoy is but a forecast of its extensive use in theatres generally.

THE TRANSMISSION OF POWER BY ELECTRICITY.*

By Ll. B. Atkinson, Esq.

The rapidly increasing importance of electrical science, and of electrical engineering, makes it of interest that in a society devoting itself to the reading of papers on, and discussion of, engineering subjects, some attention should be paid at least to the chief problems attracting the attention of electrical engineers. By no means the least important and interesting of these problems consists in the efficient transmission of power from a source where it may be cheaply produced, to places distant or near, in large or small quantities.

Many attempts have been made to devise means for attaining this desirable result, the chief agents being water, ropes and belts, and air. Taking the last of these first, that is to say, air, a host of reasons at once are seen which practically exclude it from the transmission of any large amount of power. The chief of these is its great compressibility, which makes it necessary to employ pumps of great capacity and size, besides which it gives out great heat on compression, whilst when it gives out the work stored in it, it becomes so cold as to clog the apparatus with snow deposited from suspended moisture. Nevertheless, for the transmission of small quantities of power it can do good service. In Paris, for instance, a system of pneumatic clocks is established by means of which every few moments an impulse is given, by an apparatus at a central station regulated by a very accurate clock, to an air chamber, the pressure of the air is transmitted by pipes to the clocks, which have in themselves no regulating apparatus, and thus every quarter-minute, say, the hands are moved on. Again, the machine used at the Central Post Office for punching the perforated strips of paper used in the Wheatstone automatic telegraphic apparatus are actuated by compressed air. It will be unnecessary to remind you of the Westinghouse and other air brakes, or of the rock drills and tunnel borers worked by compressed air. All these are merely examples of the use of compressed air for the transmission of power.

The next agent I have enumerated is ropes and belts. Taking belts first, these for moderate distances, as in a workshop, are invaluable, and, on the whole, are a good method of producing motion at a distance. To use belts to the greatest advantage great speed is necessary, for the following reasons:—The work transmitted by any belt in a given time is measured by the difference of tension on the tight and slack sides multiplied by the distance through which the belt runs in that time. In order to use light and therefore cheaper belts, we must make the strain small and the distance great, that is, the belt must run fast. Besides this, for a belt running at a slow speed, there must be an excess of tension on both sides of the belts to secure adhesion, and this necessitates stronger belts, whilst, if a wide belt run very rapidly, a vacuum seems to be produced under it, so that the pressure of the air produces the necessary adhesion without excess of tension. To produce these effects the belt should be 3ft. to 5ft. wide, and should run at about 6,000ft., or more than a mile per minute.

The transmission of power by ropes, particularly wire ropes

Fig. 1.—Pulley.

Fig. 2.—The Relay Rope System.

which method was invented by Hirn, is much used in Germany, and with good results. The ropes should be of iron wire twisted on to hempen foundation. The pulleys must be V shaped, the bottom of the V being lined with leather. The ropes are worked on what are known as relays, that is about every 500 feet, the driving pulleys are made with two grooves, one rope ends, and another begins. The chief wear of the ropes takes place at the intermediate pulleys, which are necessary to support the rope. The ropes have to be renewed every year. The pulleys have to be relined with leather every two or three years.

Thus we have the very considerable disadvantage of expense attending this system of transmission of power.

The first I mentioned, viz., water, has at present by far the largest use and most extended application. This system has been brought to great perfection by Sir W. Armstrong. Briefly, the process is this. We have a large cylinder, in which works a piston or ram, supporting an immense load of scrap iron or

* A Paper read before the King's College Engineering Society. Printed by permission.

Digitized by Google

bricks; this forms the accumulator. Water is pumped into this, thus raising the ram from the cylinder. Strong pipes are led to the point where the power is required. Here we have a smaller cylinder, with piston, which is acted upon when required by the pressure of the water. The advantages of this system are, 1st, the incompressibility of water; 2nd, the fact that the statical pressure which may be obtained is only limited by the strength of the materials of which the cylinder, ram, pipes, &c., are composed. But this system has several very serious disadvantages. 1st, friction. The friction over great lengths of pipe, particularly if it contain many bends, is very great, and moreover is proportional to the square of the velocity with which the water moves, and as all friction means loss of power, it is only when slow motion of the water is required that this system can be economically used. 2nd. If we want to transmit power intermittently, a very powerful objection exists in the large mass of water which it is necessary to set in motion, or, in other words, the great inertia of water which necessitates an expenditure of energy, and which energy when the motion is stopped is wasted, as heat, and which, were not air chambers provided, would burst the pipes.

The ordinary pipes for hydraulic work are 4″ to 5″ diameter, say 4″. Now, suppose we take a length of 100 yards, the volume of water $= \pi r^2 \times 300$ cubic feet $= 3{\cdot}15 \times (\cdot25)^2 \times 300 = 59{\cdot}06$ cubic feet. The weight of a cubic foot of water is about 63lbs. The mass is, therefore, $\frac{63}{32}$, which is sensibly equal to two units of mass. The mass of water is, then, 118 units of mass.

We know that the energy of motion of any body is

$$\tfrac{1}{2} m v^2.$$

The ordinary pressure in such accumulators is 800lbs. per square inch. The pressure on the cross section of the pipe $= \pi r^2 \times 800 = 3{\cdot}15 \times 4 \times 800 = 10{,}080$lbs. Every foot the water moves forward, 10,080 foot-pounds of work are done. To transmit one horse-power—that is, 550 foot-pounds—per second, the water must move with a velocity of $\frac{550}{10{,}080}$ feet, that is, 0·05 feet per second.

Putting this value in the above formula, $\frac{1}{2} \times 118 \times (\cdot05)^2 = 14{\cdot}75$, or, in 100 yards, 14·75 foot-pounds of energy are absorbed to set the water in motion; over a long distance, and transmitting greater power, this would be immensely increased.

The friction of solids depends, as is known, not on the area in contact, neither does it depend on the velocity, but only on the pressure, and the nature of the surfaces in contact. The friction in the case of liquids is precisely opposite in nature; it does not depend on the surfaces in contact, it does not depend on the pressure, but depends on the area of wetted surface, and on the velocity. The real place where the friction takes place is in the interior of the moving liquid, every particle revolving over its fellows.

Moreover, water cannot flow in a discontinuous curve; every bend produces an eddy, where energy is wasted. From all these considerations, we see that to employ water profitably we must have great pressure, acting through a small distance.

The limit to the pressure that may be used is practically defined by the great thickness of the pipes that are required, and by the difficulty of making joints, &c., watertight; 700lb. or 800lb., as I have before stated, is the usual pressure, though Mr. Twaddell uses as much as 1,400. I have now briefly sketched out the methods of transmitting power; if time permitted I should like to have gone more fully into them, but I must pass on.

In any system of transmission of power we have to consider mainly three things—*Economy, Efficiency, Effectiveness.*

These three may appear almost synonymous; but, although closely related, they are entirely distinct and separate. To give an example: An economical way of transmitting power would be to pump water up by means of a water-wheel, and then to let it flow to the required place, and there use another water-wheel. This would be economical, because we utilise a source of power costing nothing, but it would not be *efficient.* The *efficiency* of any machine, or series of machines, is the ratio of the work given out to the work put in.

Or, again, to transmit power by electricity generated by batteries would be highly efficient, but not economical.

We may transmit very small supplies of energy by means of a ray of light or heat, thrown by a mirror; this is efficient, it is certainly economical, but it cannot be called effective.

We can hardly say off-hand what will be the efficiency of any system of transmission unless we know the distance in all cases; in the case of belts we must know the speed, in the case of water the pressure, in the case of electricity the size of wire and the amount of current.

I will now, however, give the results of calculations giving us the general form for the efficiency of two of the systems mentioned, viz., water and ropes.

Efficiency of Transmission by Wire Ropes.

Let h = horse-power lost in friction,
$h = a\,(\cdot01\,n\,\mathrm{H} + \cdot025\,\mathrm{H})$ (Unwin's formula),
where H = horse-power put in, and n = number of 1,000 yards transmitted over.

Every relay is about 500 feet, so the number of relays will be $n \times \frac{3{,}000}{500} = 6n$; call this number of relays n'.

So $h = \cdot06\,n'\,\mathrm{H} + \cdot025\,\mathrm{H}$;

$$\therefore \text{ the efficiency } \frac{h}{\mathrm{H}} = (\cdot06\,n' + \cdot025). \quad . \quad . \quad . \quad . \quad (1).$$

Another rule gives—

$$\text{Efficiency} = \left(96\,\frac{n+2}{2}\right) \text{ per cent.} \quad . \quad . \quad . \quad (2).$$

Suppose we take ten relays, (1) gives $\cdot6 + \cdot25 = 85$ per cent.; (2) gives 96^6 per cent. $= 80{\cdot}13$ per cent.

Loss of Energy in Transmission by Water.

Let h be the head of water in any reservoir, the velocity of discharge, if there were no friction, is

$$v = \sqrt{2gh}.$$

If there is friction, we virtually diminish the head so far as the flow is concerned. Let the reduced head be $\frac{h}{\mathrm{F}}$.

F is of the form $\frac{4fl}{d}$, where f for iron $= \cdot0058$, for pipes lined with pitch $\cdot0042$.

$\therefore \mathrm{F} = \frac{\cdot0232l}{d}$, the quantity of water discharged per second is

$$\frac{\pi d^2}{4} \times v = \frac{\pi d^2}{4} \times \sqrt{2g \times \frac{hd}{\cdot0232l}} = 41{\cdot}3\sqrt{\frac{hd^5}{l}} = \mathrm{Q} \quad (1),$$

where d is diameter of pipe in feet.

The loss of energy due to friction is $\mathrm{Q} \times h$, where h is the loss of head due to the length of the pipe, and

$$h = \frac{\mathrm{Q}^2 \times l}{d^5 \times (41{\cdot}3)^2} \text{ from (1).}$$

Let P be the pressure in lbs. per square inch of the water being transmitted, then $\frac{\mathrm{P} \times 144}{62{\cdot}4} = \mathrm{H}$ is where H is the equivalent head of water producing the pressure,

and $\frac{\mathrm{Q} \times \mathrm{H} \times 62{\cdot}4}{550}$ = horse-power being transmitted

$= \frac{\mathrm{Q} \times \mathrm{P} \times 144}{550} = \cdot262\,\mathrm{Q}\,\mathrm{P}$ = horse-power being transmitted, call it E (2).

From (1) loss of energy $= \frac{\mathrm{Q}^3 \times l}{d^5 \times (41{\cdot}3)^2} \times \frac{1}{550} \times 62{\cdot}4$.

From (2) $\mathrm{Q} = \frac{\mathrm{E}}{\cdot262\,\mathrm{P}}$ $\therefore$ $\frac{\mathrm{E}^3 \times l \times 62{\cdot}4}{(\cdot262\,\mathrm{P})^3 \times d^5 \times (41{\cdot}3)^2 \times 550}$ = horse-power lost.

Horse-power lost $= \frac{\mathrm{E}^3 \times l}{p^3 d^5} \times \cdot00025$.*

Efficiency $\therefore = 1 - \frac{\mathrm{E}^3 \times l}{p^4 d^5 \cdot00025}$,

for $\mathrm{E} - \frac{\mathrm{E}^3 \times l \times \cdot00025}{p^4 d^5}$ is the horse-power arriving at other end.

h is in feet, l in feet, d in feet.

We now come to the transmission of power by electricity, and here I am placed in a difficulty, not knowing what knowledge of electricity and magnetism I am to assume possessed by the members of this society. It will, perhaps, be best to give a few preliminary explanations, and I can only hope that those who do not need them will not feel dissatisfied. It will be unnecessary for the present purpose to make any mention of the properties and nature of statical electricity, or electricity at rest, since all my remarks have to do with electricity in motion.

I suppose every one knows what is meant by a voltaic battery, an apparatus in which electricity is set in motion by means of a peculiar condition of dissimilar substances in contact, which condition is maintained by the oxidisation of some of the materials of the battery.

There are three terms which it will be absolutely necessary for

* Professor Perry's Cantor Lectures.

Digitized by Google

me to explain before I go any further. These are "electromotive force and difference of potential," "current of electricity," "resistance" of a circuit. Electromotive force is a term applied to that force which tends to set electricity in motion, and must not be confused with a mechanical force produced by electricity in motion.

The potential of any point is numerically equal to the *work* that must be performed to bring a + unit of electricity from the earth to that point, and conversely is the work that would be performed by a + unit of electricity in passing from that point to the earth.

If there be two points at different potentials the difference of potential between them is the work performed in carrying a + unit of electricity from the one point to the other, and, conversely, the difference of potential is the work done by a unit of electricity in travelling from the point of higher to the point of lower potential.

Any two points at different potentials will, if joined by a conductor, tend to become of the same potential, this tendency manifesting itself as a flow of electricity from the one to the other.

Thus the only idea intended to be conveyed by potential is an idea of work done by electricity in motion between points of different potential.

If W be the work done by the unit in passing between two points at different potentials, and Q = the number of units, then $\frac{W}{Q} = V - V'$, where V and V′ are the potentials of the two points. This defines E.M.F. as the rate of doing work per unit of current.

A difference of potentials is, therefore, an electromotive force, but an electromotive force is not necessarily a difference of potential.

I will next make a few remarks about the term current of electricity. As I have just remarked, whenever two points at different potentials are joined by a wire, there is a tendency for electricity to pass between the two points and produce equilibrium. Now when electricity passes between two points we *assume* the existence of a *current* of electricity. The term current obviously connects itself with the hypothesis that electricity is a fluid; still, though this idea is upset, it is convenient to call the passage of electricity along a conductor a current. The term resistance is intended to denote that property of bodies in virtue of which it takes time for electricity to pass through them. Bodies of small resistance which are called good conductors allow a large quantity of electricity to pass through them in a short time, bodies of high resistance allow only a small amount to pass through them in given time, and hence are called bad conductors. I now want to try to explain to you a most important relation which holds good between these three things I have been talking about, viz., electromotive force or difference of potential, current, and resistance.

The relation I speak of is comprised in what is known as Ohm's law, from the name of its discoverer.

Ohm's law states that the strength of the current in any circuit varies directly as the *electromotive force*, and inversely as the *resistance* of a circuit. This is extremely important, and I must ask you to pay special attention to it, as I shall refer to it again very soon.

This may be written down—

$$C = \frac{E}{R}, \text{ or } C\,R = E, \text{ or } \frac{E}{C} = R.$$

By the strength of the current is meant the quantity of electricity which passes in a unit of time—in a second, in fact.

Not only do these relations hold in abstract formulæ, but, choosing proper units, they are numerically true.

I have not time here to go into the question of units, interesting as that question is; I can only state that the units employed by electricians are multiples of centimetre gramme second (C.-G.-S.) units, which system of units must in the end supersede all others.

The name given to the unit quantity of electricity is a coulomb, and a current of such strength that one coulomb per second passes any point is called an ampere, the unit difference of potential is one volt, which is very nearly equal to the electromotive force of a single Daniell cell. The unit of resistance is called an ohm.

So, as I stated above, we may use these units in Ohm's law, and the results we shall obtain will always be true.

An example will make this clear. Suppose we have 9 Daniell cells producing an electromotive force of 10 volts, what current shall we get through a circuit of 5 ohms total resistance? We have only to divide 10 by 5, and we get the answer—2 amperes.

$$\frac{E}{R} = C\,.\,\frac{10}{5} = 2.$$

Now for a few words with respect to magnetism. Every one knows, of course, what a magnet is, viz., a piece of steel which has the property of attracting iron and a few other substances, and that two magnets will repel or attract one another, according as similar or dissimilar poles are presented to one another's action.

Every magnet is said to have a field of magnetic force, that is to say all the space around it is under the influence of its magnetic action. Every force must have two elements included in any description of that force, these are magnitude and direction.

We may draw a magnet surrounded by a field of force, such that we may show both the magnitude and direction of that force at any point by the number of lines of force which shall cut a unit area (a square centimetre) at that point, such area being perpendicular to the direction of the force. I shall presently show the importance of thus mapping out the lines of force due to a magnet.

Fig. 3 shows such a field mapped out for a simple straight bar magnet having the poles at the two ends.

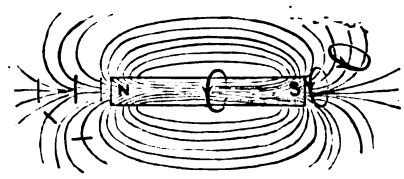

FIG. 3.

Now, I must mention a few of the relations between conductors carrying electric currents and magnets.

Suppose we pass a current through a long helix of wire, the coils of which are not in electrical contact, we obtain effects exactly similar to those shown by magnets. We get attractions for iron, we get attractions and repulsions between the dissimilar or similar poles of two such helices, and between a solenoid, as such a helix is termed, and a magnet, we get relations similar to those holding between two magnets.

By passing a core of soft iron down the helix, the iron becomes magnetised, and behaves just as a steel magnet, but the moment we stop the current, the magnetism ceases.

So we see that by means of a current of electricity we can produce magnetism, further by magnetism we can produce a current of electricity. In the discovery of this fact Faraday would have immortalised himself had he done nothing else in his life. As a matter of fact the production of a current by the motion of a magnet is a necessary consequence of the production of magnetism by a current, provided we admit the truth of the law of indestructibility of energy. I have not time here to give the proof of this.

To make a general statement it can be shown that, whenever we make any alteration in the number of lines of force passing through a coil of wire, we shall produce a current in that coil, and the electromotive force produced in the coil is directly proportional to the number of lines added or subtracted in unit time. It is also proportional to the number of turns of wire in the coil.

It is on this principle of the alteration of the magnetic field passing through coils that all the magnets and dynamo electric machines of the present day are constructed. They consist of two parts; 1st, the magnets, which may be permanent steel magnets, in which case we call it a magneto-electric machine, or they may be electro-magnets, formed by the passage of the current in the way I have above described. These produce the necessary magnetic field. 2nd. We have what is generally called the armature, which contains the coils, which are moved from one part of the magnetic field to another, thus producing the necessary alteration in the number of lines of force passing through the coil. In addition to this, if the machine is to furnish a current in one direction only, it must have a commutator, which is a contrivance which reduces all the currents produced in the coils to a common direction.

(TO BE CONTINUED.)

PROVISIONAL ORDERS.

APPLICATIONS TO THE BOARD OF TRADE, 30TH NOVEMBER, 1882.

The following is an alphabetical list of the towns for which provisional orders are being sought, together with some statistics, which we think may be interesting to our readers. We are

MEDITERRANEAN EXTENSION TELEGRAPH COMPANY (LIMITED).

An extraordinary general meeting of this Company was held at the Cannon-street Hotel on the 1st inst., "for the purpose of considering the offer which has been made by the Eastern Telegraph Company to purchase the telegraph lines and property belonging to the Mediterranean Extension Telegraph Company, upon the terms set forth in a letter from the solicitor of the Eastern Telegraph Company (a copy of which letter has been furnished to each shareholder), and to pass such resolutions as the majority of the shareholders may think proper." Mr. James Carmichael presided.

The SECRETARY (Mr. Tombs) having read the notice calling the meeting,

The CHAIRMAN said: Gentlemen, it will be within the recollection of all of you—at all events of all those present who were at the last meeting on the 31st August last—that I then informed you that negotiations were pending with the Eastern Telegraph Company for the purchase of our property. I told you then that these negotiations were not in a state that we could bring them before you, but that as soon as any definite proposal was made we should, before taking any further steps in the matter—before moving in any way to compromise your interests—lay the whole question before you and take your opinion before acting in the matter, and it is with this object and with this view that a circular has been addressed to you enclosing the absolute offer in the letter of Mr. Burt, the solicitor of the Eastern Company, that you might yourselves form an opinion of the offer and come here, meet together, and consult upon it. Now, I need not tell you that it would have been much more pleasant to us, the directors, had the offer been couched in a more liberal spirit, but, such as it is, it is our duty to lay it before you, and take your advice and have your opinion upon it, before either declining or accepting it, or doing anything with it. We could not to-day decide anything positively, or do more than ascertain the wish of the majority of the shareholders. If you were to decide on selling your property, it would then be necessary to call a special meeting, and I believe—our solicitor is present, and will correct me if I am wrong—we should have to go into liquidation, a friendly liquidation, and to appoint liquidators, and the Company would require to be dissolved. The liquidators would then sell the property to the Eastern Company. I think that that is the legal form, but the first thing is to ascertain your wish and the opinion of the meeting. Therefore we have asked you to come here to-day, and shall now be most happy to answer any questions you may put as far as we can, and consult with you on the best steps to be taken.

Mr. WILLIAM FORD desired to say that he did not object to the terms proposed, but, as an ordinary shareholder, he strongly objected to the proposed apportionment of the reserve fund in the manner stated in Mr. Burt's letter. He contended that it was beyond the province of the Eastern Company to make any suggestion as to the distribution of the reserve fund, which he held was entirely a question for the shareholders themselves. He trusted that if the meeting gave their assent to the proposal, it would be understood that they did not give their assent, either directly or indirectly, to the apportionment of the reserve fund, which had been created at the expense of the ordinary shareholders.

The CHAIRMAN said he quite agreed with Mr. Ford that the distribution of the reserve fund was entirely a shareholders' question. Mr. Burt's remark as to the reserve fund was only a suggestion, however.

A SHAREHOLDER inquired in what way the preference shares were preference shares.

The CHAIRMAN said that the preference shares had been raised on two separate occasions, many years ago, with the object of laying down new cables. In further reply to the shareholder, he added that the shares were only preference as regarded dividends.

Captain TURNER desirered to know if the directors recommended the offer which had been made by the Eastern Company.

The CHAIRMAN: The directors have carefully abstained from making any recommendation for or against it. I think it is much better that we should leave this question as a shareholders' question. If you ask me my opinion, I will give it, but not as chairman of the board. It is a difficult subject to give an opinion about, as I might be accused afterwards of giving an opinion in favour of an offer that might prove disadvantageous. It is quite a shareholders' question, and I have my opinion of it as a shareholder.

Captain TURNER remarked that the directors must know a great deal more about it than the shareholders.

Mr. ADAMS suggested that the chairman should give his opinion of the offer as a shareholder.

The CHAIRMAN: Well, there are shareholders and shareholders. There are original shareholders, and I am one of them, who unfortunately paid £10 a share. There are those who came in on much more favourable terms, varying from £2 and £3. Then there preference shareholders. There are so many shareholders who must have, to a considerable extent, different interests. As an original shareholder, and as having paid the full value for my shares, I say that I do not wish to part with my property at the price offered. Many others may think it desirable to accept this offer, and I should not like to stand in their view. Whatever may be the shareholders' wishes, we shall carry out loyally. We thought it our duty to point out to you the worst that could happen to you—that the Government guarantee ceases from the 4th of this month, in four days more; and then, if we go on, we must rely entirely upon our own resources for earning any dividend at all, and at the present moment we should not be able to pay the ordinary shareholders anything. We could, I presume—indeed I know—we could pay the preference shareholders something, but not eight per cent. There are prospects of improving the traffic, and, as you know, the Mediterranean is a big lake, and the Eastern Company may not always have the monopoly of the lake. We have an important position at Malta, and we might have other offers. We must not deceive ourselves, however. If we go on we shall have to rely entirely on our own resources. There is another thing I must tell you. I do not see that we can work much more economically than we are doing. We have been under Government supervision, we have had a Government director on our board, and we have worked with the greatest economy. I do not think we could cut down much more. The Italian concessions are mentioned in our circular. One of them has seven, and the other nine years to run, and they are exclusive concessions as regards Sicily and the South Coast of Italy.

Mr. ADAMS thought the directors should know pretty well what the resources of the Company were, and in face of what the chairman had said as a shareholder, he thought they should not deal with the Eastern Company on the very low terms which had been offered. There was scarcely anything for the ordinary shareholders, who, he said, would have to take 20 per cent. off the amount of the 4 per cent. debenture stock.

The CHAIRMAN: Hardly as much as that.

Mr. ADAMS (continuing) suggested whether it would not be desirable to see if something better could not be done rather than give up the Company altogether on the terms offered, particularly as they had an offer of something like double the present amount twelve months ago.

The CHAIRMAN: No; this is the first definite offer we have ever had in writing, and I wish it had only been more liberal.

Mr. ADAMS remarked that had the offer been more liberal it would have been accepted; and a more liberal offer could have made very little difference to such a powerful company as the Eastern Company. He thought shareholders should be guided by the opinion expressed by the chairman that the offer was not sufficient. The debenture stock offered was not as if it were on land or on a railway. If they had a war and could not get to their "rope," what would the debenture stock be worth? Perhaps the meeting might be informed how far the shareholders had given their opinion by proxy respecting the offer. As far as he could see the Company would earn considerably more for the preference shareholders than the preference shareholders would get by accepting the offer.

The SECRETARY remarked that the earnings last year would have given the preference shareholders 5 per cent.

The CHAIRMAN stated that they had sent out proxies to every shareholder, but not a fourth of the capital was represented by them. There were about 83 shareholders in favour of the offer, 13 against it, and 20 had sent their proxies to the directors to vote as the directors thought best. He, however, did not think it was quite fair to wish to place such a responsibility on the directors. 693 shares were represented by the proxies of the preference shareholders. The proxies were almost entirely from ordinary shareholders. There was but a very small amount of preference shares. He inquired whether any preference shareholders were present who would give their opinion of the offer.

Mr. VEARES stated that he had read the circular which had been sent out by the directors impartially, and he had gathered from it that they recommended the offer.

The Hon. A. PONSONBY dissented.

Mr. VEARES stated that the document had been sent out from headquarters, and he certainly thought it urged the importance of a decision,

Digitized by Google

terms having been put forward with that object. He was surprised at the little expression of opinion among the shareholders as to the offer. The chairman had said that he had paid £10 for his shares, and was sorry that the offer was not better, and they had had a few remarks from another shareholder, but he (Mr. Veares) thought that the present was the time to elicit opinions from one another on which the Board might base their views. He confessed that he did not know how to decide. If forty out of fifty were for it he should go with the forty; but two gentlemen had spoken, and had placed before them such confounded difficulties that he did not know how they were to act. He would ask the Eastern Company whether as regarded the offer they had made they were doing unto others as they would be done unto. They wanted this Company's property, and they came forward and made an offer when the market was depreciated. He was neither opposed to nor in favour of the offer, but he did complain of the nothingness of the chairman's remarks. The offer was very small, but it now appeared from what one gentleman had said that there was something to come off even the £1 12s. that was offered for the Ordinary shares. He thought that the Eastern Company's debentures were at something like 100.

The CHAIRMAN said that there were no debentures of the Eastern Company in the market.

Mr. NICHOLLS suggested that the meeting should be adjourned, and that a committee of two ordinary and one preference shareholders should be appointed to confer with the directors and report to a subsequent meeting as to the desirability of the offer being accepted or rejected.

Mr. J. L. CUTHBERTSON thought that previous to such a motion being put there should be further discussion. He was an original shareholder, not a preference shareholder, nor had he trafficked in the shares from the commencement. He asked the chairman if he was connected, directly or indirectly, with the Eastern Company.

The CHAIRMAN: I am not.

The Hon A. PONSONBY and Mr. C. H. ROBINSON also replied that they were not.

Mr. CUTHBERTSON thought the answer satisfactory, and observed that the preference shareholders, having regard to the position which they occupied, had been receiving a large dividend for a number of years, seeing that they could only receive what the Company might earn. He, therefore, thought that the difference in the price offered for the preference and the ordinary shares was preposterous, because if the Company was earning nothing, or only a trifle, the preference shareholders could not be in a different position from the other shareholders. He did not see why the Company could not go on. If the preference shareholders met the ordinary shareholders in an equitable manner, and reduced their interest, he thought the ordinary shareholders might contrive, with the aid of the reserve fund, strict economy as regarded the salaries to the officers, and remarkably small fees to the directors, to go on. He was an original shareholder, like the chairman, and he did not feel inclined to receive 24s. and five-eighths per cent. for his money. In fact he would almost lose the lot. He thought the preference shareholders might fall in with his views at a subsequent meeting. He did not think that the shareholders, either original or preference, should accept the present offer. Before they proceeded further, he thought what he had said might be considered.

Captain TURNER would make one more appeal to the chairman and directors, and thought in a matter such as this they should give their opinion and advice regarding the offer, since they knew the whole circumstances of the case.

The Hon. A. PONSONBY said that he had been asked to give his opinion of the offer as a director, but that he declined to do. The Board had been called upon to get certain terms from the Eastern Company, and they now brought them to the shareholders to decide upon. As the chairman had very ably remarked, there were some shareholders who had given £10, and others £5, while some gave £2 for their shares, or even less. Those who had given less might make something out of the sale, but those who had given £10 would lose. Consequently the directors as directors could not give them advice as to the offer. Speaking as a shareholder, however, he unhesitatingly said that he objected to the proposal; but, notwithstanding, he should go in accordance with the shareholders' wishes. He held 170 shares, and should vote with the majority, whichever way it went; but, individually, he was opposed to the offer, which he regarded as the very minimum that could have been made. In the twenty-four years they had existed they had paid the Eastern Company as intermediaries £7,000 a year. There was no doubt that, with speculation and with business improving, other lines would be opened up throughout the Mediterranean, and they could show a profit to Alexandria to someone who would lay down a wire of £7,000 a year. They had still the concessions referred to from the Italian Government, and he did not see why they should sell their concern at present, when they were at their very worst. He had the greatest respect for many of the gentlemen connected with the Eastern Company, but he did not believe they would give sixpence more than they could help. As to the fees of the Board, the directors would be willing, if the Company went on, to meet the views of the shareholders, although they certainly did not get much. As regarded the salaries to the officers, however, they were as low as they could be and much reduction could not be expected. The Government last year paid £1,760 for the repair of one of the Company's cables; but, in future, if they went on, they would have to bear the cost of repairs themselves. The letter of the Eastern Company showed the worth of the property at the market price, and he did not wish to give any opinion as to the relative rights of the preference over the ordinary shareholders.

Mr. C. H. ROBINSON, speaking not as a director, but as an independent shareholder, acquiesed in the views of the chairman and Mr. Ponsonby. He had been a shareholder in the Company for a great number of years, and when he sat on the shareholders' side of the table he had always advocated the necessity of an amalgamation with the Eastern Company. Since he had been a director his endeavours had always been directed to produce that result. He had an interview with Sir James Anderson, the result of which he communicated to them some ten or eleven months ago. It was a proposition to give the ordinary shareholders £2 10s. in money, and for the preference shares a debenture stock and three per cent. for it. That was submitted to a meeting some time ago, and the sense of the shareholders, one and all, was that they would not take less than £3 for the ordinary shares. That communication was made to the Eastern Company, who, he believed, made the matter nugatory for the time being. Since then negotiations had been passing between them, and they had resulted in the present offer, and how the discrepancy had arisen in eleven months between £1 12s. and £2 10s., he could not see. In his opinion the Eastern Company wanted this Company's line, but if the shareholders resigned all power over their property they would entirely shut themselves out from any benefit arising out of the chapter of accidents that were daily occurring in their own experience of new companies being brought forward and their receiving better offers. There were always persons who, if there was a basis to go upon, thought they saw a chance of making an extension of that basis. Mr. Ponsonby had told them what this Company paid to the Eastern Company annually for messages going over their lines, and if a cable of this Company's, which was now lying dormant, was raised up, and a company was started to go to Alexandria, they would so tap the Eastern Company that they would pay a very handsome dividend on this Company's property as well as to any one who would lay a cable to Alexandria. They had paid to the Eastern Company altogether for messages going over their line £165,000.

The CHAIRMAN observed that loose calculations ought not to be made.

The SECRETARY stated that he had taken the figures out.

Mr. ROBINSON observed that the 4 per cent. debenture stock which the Eastern Company offered would not be worth more at the outside than, say £85 to £90, and therefore the actual offer of £1 12s. would be considerably reduced. The £40,000 which the Eastern Company offered them in debenture stock would be, at 4 per cent., £1,600 a year; but they would save almost the whole of that in working and other expenses, as their Company could do this Company's work at very little more cost than their present expenditure. He calculated that the Eastern Company would be getting this Company's property, if they sold for the present offer, for about £400 a year. As a shareholder the offer appeared to him to be sadly too low, and the least minimum market price had been taken. He believed that that day they could get in the market £1 17s. 6d. for that which the Eastern Company offered £1 12s. for. However, it was a shareholders' question, and the directors did not wish to bias in any manner the opinions the meeting chose to advocate, which the directors would faithfully carry out.

The CHAIRMAN, in reply to Mr. Beck, said that he believed that in the event of the offer being accepted the Eastern Company would take over some of the Company's staff at Malta, but none here; nor did he think they would take over any of the Corfu staff, where one gentleman had been with this Company for twenty-four years. He thought it would be the duty of the directors to compensate their officers. Their secretary had been with them for thirteen years, their head clerk eleven years, and one of the officers at Malta twenty years.

A SHAREHOLDER inquired what steps had been taken to obtain a renewal of the agreement with the Government.

The CHAIRMAN stated that he had addressed a letter to the Secretary of the Treasury which was very short, and gave a little history of the Company. The letter was dated the 25th August last, and was as follows:—"Sir: I have the honour to submit the following proposal on behalf of the Mediteranean Extension Telegraph Company, which I trust may meet with the consideration of the Lords Commissioners of the Treasury. This company was originally constituted under the sanction of the Governments of Great Britain and Sardinia in 1857 with the object of connecting the islands of Sardinia, Malta, and Corfu by submarine cable, and a guarantee of 6 per cent. per annum was given by Her Majesty's Government on £120,000, the original capital of the company, for a period of twenty-five years. The cable between Cagliari (Sardinia) and Malta was subsequently destroyed by volcanic eruption at the bottom of the sea; and the line between Corfu and Malta being also interrupted, a fresh arrangement was made with Her Majesty's Government by which the guarantee was confirmed, the company laying down two new cables—one between Malta and Sicily, and the other between Corfu and Otranto—to replace the original cables which had been lost. The traffic on both those lines, and especially on that between Malta and Sicily, proved very satisfactory, and during several years only a small amount of the guarantee was required from Her Majesty's Government, and between the years 1863 and 1866 no call whatever was made on the Treasury in that respect. In 1869 the Anglo-Mediterranean Telegraph Company, now the Eastern Telegraph Company, duplicated their line between Malta and Alexandria, and called upon the Mediterranean Extension Company to lay a second cable between Malta and Sicily, as they maintained that one line would prove insufficient for the traffic between Alexandria and the European continent. The Mediterranean Extension Company accordingly raised additional capital and complied with the request. But shortly after the establishment of this second line between Malta and Sicily, the Anglo-Mediterranean Company extended their line from Malta to Gibraltar, and thence to Lisbon and Falmouth, and thus diverted to their new route all the messages between England and the East which had hitherto passed over the wires of the Mediterranean Extension Company. A concession was subsequently granted by the French Government to Baron Erlanger for the establishment of telegraph lines between Marseilles and Bona (Algiers), and from Bona to Malta, and Her Majesty's Government, notwithstanding the earnest protest of the Mediterranean Extension Company gave permission to Baron Erlanger to land and work his cable at Malta, which naturally proved most prejudicial to the interests of both the Company, and Her Majesty's Government, as these new lines, which were afterwards sold to the Eastern Telegraph Company, abstracted all the traffic between Egypt and France which had been previously transmitted by the Mediterranean Extension Company's cable, *via* Sicily and Italy. I would, however, beg to draw my lords' attention to fact that notwithstanding these heavy blows, and the severe loss of traffic sustained by the Company, they continued to manage their business with so much economy, and with such partial success that up to the present moment the average payment made by the Treasury has only amounted to £3,231 per annum, while under the guarantee Her Majesty's Government were liable to the payment of £7,200 per annum, or more than double the amount actually received by the Company. But the period of terminating the agreement between Her Majesty's Government and the Company is now approaching, and it will legally become void on the 2nd of December of the present year. I am, therefore, induced to lay this short statement before my Lords, and to solicit the renewal of the guarantee of Her Majesty's Government in such a modified form as they may consider advisable. I am aware that telegraphic communication with Corfu is no longer of any importance for Government purposes, but I venture to sub-

Digitized by Google

mit that it would be clearly to the advantage of Her Majesty's Government to grant a small subsidy rather than abandon an existing telegraph line with Malta, by which messages could be sent to and from Great Britain, either through Italy and France or through Italy and Germany. Should the cables between Malta and Gibraltar, or between Gibraltar and Lisbon and Falmouth become at any time interrupted, this alternative line of communication might prove invaluable to British interests and Her Majesty's naval and military departments, especially in the event of certain political complications in the Mediterranean, which might possibly develop from the present critical state of affairs in Egypt. The Mediterranean Extension Company could not, however, hope to continue the working of this line between Malta and Sicily in face of the severe competition already mentioned without some encouragement and support from H.M. Government, and I therefore trust my Lords may be induced to grant a renewal of a portion of the present guarantee on condition of the line being maintained in good working order." That is signed by myself as chairman of the Company, and a copy of it was forwarded to H.M. Secretary of State for War and to the Lords Commissioners of the Admiralty for their information, and from them we have had an acknowledgement of the receipt of the letter. On the 17th October we got this answer from the Treasury:—"Sir: I have laid before the Lords Commissioners of H.M. Treasury your letter of the 25th August last, requesting that the guarantee of H.M. Government might be continued to the Mediterranean Extension Telegraph Company (Limited) after the expiration of the present agreement on the 2nd of December next. I am directed, in reply, to inform you that my Lords regret they can hold out no hope of a prolongation of the present agreement after its expiration on the 2nd of December next, or of a renewal of the guarantee of H.M. Government in a modified form." That is signed by Mr. Courtney. You see from that letter that we have done our best, and that the Government decline to do anything further. In fact, as I said, we are left to our own resources, and it appears to be the general opinion of the meeting that we can rely on those resources. If you wish us to appeal to the Eastern Company to see if better terms can be obtained we will do so, and perhaps that would be the best course.

Mr. Adams thought there was an amendment before the meeting.

The Chairman did not think the amendment had been seconded.

Mr. Adams thought that the feeling of the meeting was that the matter should be postponed, seeing the difference in the amount offered previously and that offered now. If the affair were postponed for three months, they might see whether something better could not be obtained.

Captain Turner: I beg to propose "That this offer of the Eastern Telegraph Company be rejected."

Mr. Beck: I second it.

The Chairman put the motion in the usual way, and declared it carried unanimously.

The Hon. A. Ponsonby (to Mr. Adams): Then will you move that the meeting be adjourned for three months?

Mr. Adams: That had better be left.

A vote of thanks was then passed to the chairman, who in reply expressed his acknowledgments, and hoped the Board would hereafter be able to lay something better before them.

FAURE ELECTRIC ACCUMULATOR COMPANY (LIMITED).

An extraordinary general meeting of this Company was held on Monday last at the Cannon-street Hotel, Sir A. J. Otway, Bart., M.P., the chairman, presiding.

The Secretary (Mr. Herbert Canning) having read the notice convening the meeting,

The Chairman said: Gentlemen, you have heard the notice read convening this meeting. You are aware, therefore, of the object for which you are called together to-day. It is to formally confirm the resolution which was passed, I think with unanimity, on the last occasion on which we met. Subsequently a notice has been issued stating that possibly I might not be able to take the chair before two o'clock, and this was done to enable those who were interested in the Company to attend, as possibly statements of importance for the Company might be made. Well, that seems to me really to be the point that most interests us to-day. The confirmation of this resolution, I believe, will be a mere formal matter, and I dare say those who approved of it on the first occasion will not have altered their opinion now. Indeed, it seems to me to be the just and proper arrangement, and I am not the least surprised that you adopted it with unanimity. In regard to the statement I have to submit to you to-day I shall ask your very serious attention. I think I have said before that I always considered in all matters of business the straightforward and the most outspoken course was that which should be always taken between directors and shareholders. I do not understand any other way of conducting these matters myself, and I hope I never shall understand any other way. There may be some who are cleverer, but this seems to be the proper course to take, and I shall not depart from it. Therefore, I consider when directors have decided upon any course of action which may affect seriously the prospects of the Company, it is their duty to take the earliest opportunity to make that decision known to the shareholders. I think it almost disingenuous, and I doubt whether it would be fair to meet a body of gentlemen to discuss a formal resolution when we have an opportunity of speaking to you, and to go away without having said that which was uppermost in our minds. Therefore, I make no apology for the communication of the statement which will be made to you to-day. I will try to make it—as much as possible at any rate—intelligible and clear. Now, gentlemen, you the other day, with unanimity—with unanimity I must beg to observe—approved of the project of M. Philippart with regard to the conduct of the proceedings of this Company, and I must be allowed to say, in passing, that I recognise M. Philippart as a man of remarkable ability and of very special knowledge with regard to the accumulator, and, therefore, my impression is that in the matter he undertakes he will act for the advantage of the Company. There is every reason to hope in this case he will succeed; and if he does succeed great advantage may accrue to the concern. But, gentlemen, I am sure you will forgive me if, while saying this, I should also state that it is almost the unanimous opinion of the Board—at any rate there are those present who will be able to correct me if I am wrong—that there is one mode of conducting business that is more desirable in our view than any other. For instance I considered that if the making of the accumulator was to be done in England, and the business to be carried on in this country, it was essential that the directors of the Company should be English. On the other hand, if the making of the accumulator is no longer to be carried on in England, and the business is to be transferred to another country, then I am unable to say that English directors are the most suitable, and I am not able, neither are any of your directors able, I presume, to conduct the affairs of a company the whole of whose interest and business is in another country. Therefore, this brings me to the conclusion as to what shall be the order of our proceedings in future, and I am bound to say that in this opinion I find myself in accord with every member of the Board. I have the opinion that it would not be necessary for us, and I doubt even if we should be the most proper persons, under the circumstances to conduct this Company. I may say, speaking for myself, and I think I am speaking for my colleagues, that they have every desire to give effect to the unanimous wish or the unanimous opinion as expressed at the meeting on the occasion to which I have referred, but we do not find ourselves able to agree with the mode by which it was proposed to carry into effect the resolution then passed. Now, I do not wish to say one word against it—not a word. I think that M. Philippart will carry out what he has commenced according to his fashion, and according to the customs especially of France, but the mode of procedure does not commend itself to us. I have not been, and I am not aware that any of my colleagues have been, connected with financial operations. We consider this Company more as an industrial than a financial one, and the proposed method of procedure did not seem to correspond to our opinion of the way this business should be conducted. Therefore we came to the conclusion that the best thing to do under the circumstances was that when the new mode of procedure came to be carried into effect we should not be the persons to give effect to it. It would be better that the direction should be composed of gentlemen entirely in accord with M. Philippart and with his views. Well, we should prefer, after having come to that conclusion, that we should in the ordinary course of things have selected, or, rather, ask you to select, some gentlemen to take our places at once, but we remembered we had what we considered an obligation to discharge towards the shareholders—viz., that M. Philippart undertook, or rather the Société la Force et la Lumiere undertook through him, to give to every shareholder of this Company one fully paid-up share of the Faure Accumulator Company for two shares partly paid up which he might hold in the Company at the present moment, conferring upon him that which we considered an undoubted benefit, by relieving him of all future liability in regard to these shares—until that obligation, or undertaking, is carried out, I think we can quite well administer the affairs of the Company, and we should remain. It seemed to me right and proper, and, indeed, it seemed to be our duty to remain to see that that obligation was fulfilled. The fulfilment of that obligation does not take place till the 1st January, unless M. Philippart should previously determine it. He has until the 1st January to fulfil that obligation, and therefore we shall consider it our duty to remain in the position we are in until the 1st January, unless, as I said, the shares are previously delivered. Afterwards there is really, in my opinion, no necessity whatever that we should continue, indeed I think it would be for the advantage of the shareholders, if M. Philippart's scheme is carried out, that he should have, as I said before, gentlemen associated with him who are entirely in accord with him. I repeat once more, there is no misunderstanding, and I do not want to say a word against M. Philippart's mode of carrying his scheme into execution, or as to his skill and capacity. I believe he will tell you presently how the matter stands. There will be a pecuniary advantage to this Company, no doubt, but it is not on the lines altogether on which this Company was formed, and on which we assumed the direction. I trust, therefore, that you will think we have acted in a manner which was right and proper, and one consistent with our statements and in accordance with our obligations to you, if when the moment comes we ask you to relieve us of any further responsibility in the matter. Now, what I wish to put before you will be, first of all, this resolution, and then I think it will be interesting to all the shareholders, as M. Philippart is present, that he should make his statement to you. His interests are large. He is here to address you, and I think it will be interesting to you to hear what he has to say. I have, therefore, to ask you to confirm the resolution passed at the meeting of the 6th November last, which is as follows:—"That the scale of voting by the shareholders, as at present prescribed by Clause 64 in the Articles of Association of the Faure Company be altered, and that a clause be substituted in lieu thereof in the following terms:—'That on every question to be decided by a poll every member present, in person or by proxy, shall have one vote for every Ordinary share up to ten inclusive, and he shall have an additional vote for every five shares beyond the first ten Ordinary shares up to 100 inclusive, and an additional vote for every ten Ordinary shares beyond the first 100 shares; and the holder of every ten Deferred shares shall have the same number of votes in respect thereof, as if they were one Ordinary share, every ten Deferred shares being, for the purposes of voting, always equivalent to one Ordinary share. No member shall have more than 500 votes in all, and no member shall be entitled to vote on a poll as the holder of any shares in respect of which he shall not have been registered for three calendar months previous to the meeting.'"

Mr. W. Lean seconded the resolution, which was put to the meeting, and carried unanimously.

The Chairman: Now, gentlemen, I shall be prepared to hear the observations of any gentleman present, and perhaps it may be better if I ask M. Philippart to make any statement he has to submit.

M. Philippart (who spoke in French, Mr. Campbell officiating as translator) said that since the last meeting he had been making the necessary arrangements in order to carry out the scheme which he had laid before them. He thought it was almost settled, except the affixing to it the necessary signatures. The first thing he gave his attention to was that the Storage Company should give back to the Faure Company the 20,000 shares they held in the Faure Company upon certain terms and

Digitized by Google

conditions. The shares which the Storage Company possessed in the Faure Company were a burden for the latter and a considerable danger and difficulty if the Company ever came into liquidation from one cause or another. He did not express an opinion as to whether the Faure Company would have had to go into liquidation, but if it had continued to go on without some change in its programme he thought it might have been possible. His endeavour had been to change the whole current of the affairs of the Company, and to put it on a different basis. He thought an arrangement of this kind would be carried out—that the Faure Company should cede to the Storage Company the remainder of their English patents, the Storage Company giving back to the Faure Company the shares which they held in it, allowing the Faure Company to retain the shares which they held in the Storage Company. The result would be that if the Faure Company did go into liquidation with the funds they had remaining in their hands and the value of the shares they held in the Storage Company they would have something like £50,000 to the good. He had the greatest opinion of the Faure accumulator, and also of the Sellon-Volckmar accumulator, and he considered these the only accumulators which were of any value. He looked to a prosperous future for the Company. He had the greatest opinion of this question of electricity, but he thought that, whatever was made in England, a very much larger profit must, as a matter of course, be made upon the Continent. He considered, however, that in France alone the question of electricity was worth all the other countries on the Continent together. By arrangements which he had made he was the possessor of the patent for France and the French colonies. By these contracts becoming definite, and by this Company giving these up, they became proprietors of something like 92 per cent. of the whole patents in France for France and the colonies. He had great hopes for the future, and he reminded the meeting that he and his friends were proprietors of the largest portion of this concern. He hoped that by the end of March the shareholders would receive back a sum equal to the amount of money which they had put into the Faure Company, and they would possess beyond that a share of equal amount in the French Company—the owner of all the French patents. Whether they paid £2 per share, or whether they paid £10, they would get the whole of the money back which they had paid into the Faure Company, besides being possessors of a share of equal value in the company owning all the French patents. He could quite enter into the feelings of the directors when they said that the undertaking would be more French than English, and he agreed that the majority of the directors should be French; but he did not see why some of the gentlemen on the present Board should not remain. That was a question, however, which he could not, of course, decide for them.

In answer to a shareholder,

M. PHILIPPART said the Faure Company would not cease to exist unless the whole of the money the shareholders had paid in was given back, at the same time allowing them to hold shares of equal value in the French Company, in which case the remainder of the Faure Company's English patents would go to the Storage Company.

The CHAIRMAN, in reply to a further question, said the interests of the shareholders would then be transferred from the English to the French Company.

A SHAREHOLDER asked whether the shares given them in the French Company would be fully paid up?

M. PHILIPPART (through Mr. Campbell) replied in the affirmative, and said, in answer to a further question as to whether, in the event of all the shareholders not accepting the offer made to them, the Faure Company would be wound up, that the decision would lie with the majority of the shareholders.

After some further discussion,

The CHAIRMAN said he could not admit that there was any foundation for M. Philippart's remark that this Company might have gone into liquidation if the directors had continued to conduct its affairs on the lines they had hitherto done. He considered this observation was unjust to his colleagues. Most of the shareholders were men of business, and were, therefore, aware that in the case of a new invention much had to be done to make it known, and in the way of experiments, so that a large return could not be expected from the investment at the commencement. He contended, and should always contend, that the concern had been going on very favourably, making such progress as was consistent with new inventions of a complicated character. He had not, he was sure, said a word which could be considered hostile to M. Philippart. He had always acknowledged his capacity, but these were not schemes which had his concurrence, or which the present Board would like to enter upon. At the same time he had faith in M. Philippart's ability and knowledge of the accumulator, and it would be very gratifying to him as a shareholder if his (M. Philippart's) scheme were successful.

On the proposition of Mr. LEAN, a vote of thanks was passed to the chairman and directors for the manner in which they had conducted the business of the Company, and the proceedings terminated.

THE ORIENTAL TELEPHONE COMPANY (LIMITED).

An extraordinary general meeting of this Company was held on Monday, at the offices, 3, Great Winchester-street Buildings, E.C., Colonel Gouraud in the chair.

Mr. W. G. HALL (the secretary) read the notice convening the meeting, and the minutes of the previous meeting were also read and signed by the chairman as correctly entered.

The CHAIRMAN said: Well, gentlemen, I have the pleasure to propose for your approval the motion which you have heard read, and submit it for your confirmation. There is very little to say about this matter. But for the fact that the meeting is for the simple purpose of confirming the resolution previously passed by a very large meeting of the proprietors, it would be matter of regret that there are so few shareholders here to-day. Probably there would have been more here to-day had it not been for the very noted occasion which has occupied so many of Her Majesty's subjects in paying their customary tribute of loyalty. I am sure we should all like to be there, too, if we had good places. It is also to be noted that Her Majesty has on this day the usual Queen's weather, and I hope, and we may all hope, that it will prove an auspicious circumstance in the history of our own affairs. The number of proxies represent a very large proportion of the capital, more than 50,000 shares having been sent in. I beg to move the confirmation of the following resolution, viz.:—

That the clause or sub-section marked (*c*) contained in the 60th of the Company's Articles of Association be repealed, and that, in lieu thereof, the following shall henceforth stand and be the clause or sub-section marked (*c*) contained in the said 60th Article; that is to say:—

"(c) They may of their own authority sell all, or any part of the business, goodwill, patents or patent rights, and property of the Company, or the business, goodwill, patents or patent rights, and property appropriated for, or appertaining to, any branch of the Company's business, either wholly or partially, for cash or for shares, debentures or other interests in any company or corporation, or to any person or persons; and if deemed expedient, the directors may hold or (so that the capital of the Company be not thereby reduced) distribute in specie among the members in proportion to their holdings, or otherwise deal with such shares, debentures, or other interests."

Mr. P. CARNEGY: I have the pleasure to second that resolution.

The resolution was then put to the meeting, and carried unanimously.

A vote of thanks to the chairman terminated the proceedings.

SLIP

SPAIN.—The cable between Marseilles and Barcelona is interrupted.

THE TELEPHONE IN QUEBEC.—A telephone cable has been laid between Levis and Quebec at Victoria Cove.

BRAZILIAN SUBMARINE TELEGRAPH COMPANY. — The traffic receipts of this company for the week ended December 8 were £3,830.

THE TELEPHONE IN FRANCE.—It is said that all French barracks, in places where there are several, are to be connected by means of telephone lines.

GERMAN PATENTS.—Between May and October in this year 190 patents for inventions connected with the applications of electricity were granted in Germany.

PARA.—The cable between Fortaleza and Maranham is interrupted, and there is therefore at present no telegraphic communication between Maranham and Para.

BRITISH ALMANAC AND COMPANION.—The fifty-fifth issue of this almanac, which has just appeared, contains an article on "Electric Lighting," written by Mr. L. T. Thorne.

ELECTRIC TRAMWAY FOR SAN FRANCISCO.—Rumour says that electric motors are about to be introduced on the San Francisco street tramways. The current will be supplied by accumulators.

BRITISH GUIANA.—It is stated that telegrams are received in British Guiana in 52 minutes after leaving London, which is quick work, considering the number of stations they have to pass through.

THE EDISON SYSTEM IN SAN FRANCISCO.—The Edison Electric Light Company, of San Francisco, has been formed with a capital of 5,000,000dols, of which 3,500,000dols. was taken before the public announcement was made.

WEST INDIES AND BRITISH GUIANA.—The cables between Trinidad and Demerara, and between St. Croix and Trinidad, being now repaired, telegraphic communication is restored to all parts of the West Indies and British Guiana.

THE WESTERN UNION TELEGRAPH COMPANY. — A despatch from New York, dated Wednesday night, says:—"The surplus of the Western Union Telegraph Company, after payment of the quarterly dividend of 1½ per cent., is 3,490,447 dollars."

NOTTINGHAM TELEPHONE EXCHANGE.—The number of messages transmitted through the National Telephone Company's Exchange at Nottingham for the week ending December 7 amounted to 5,137, being an increase of 4,500 on the corresponding week in 1881.

ELECTRIC LIGHT IN NEW ZEALAND.—Preparations are being made to light the house of Sir F. D. Bell's Stag Valley Estate with the electric light, the power being supplied by a large waterwheel, from which insulated wires are to run to the residence in question.—*Colonies and India.*

ELECTRIC LIGHTING FOR GRAVESEND.—The Gravesend Town Council, instead of applying for a provisional order, have appointed a committee to confer with the South-Eastern Brush Electric Light Company on the subject of introducing the light into the town. This company, we may add, has applied for an order.

ELECTRIC LIGHT IN LONDON.—The Civil Service Supply Association, in Bedford-street, Strand, W.C., have adopted several Brockie lamps for lighting their building. The lamps outside the building give a very good light. They have been erected by the British Electric Light Company. The current is generated by Gramme machines.

THE TELEPHONE IN COLOMBIA.—The Colombia and Venezuela Telephone Company has been registered in the office of the clerk of Monmouth County, New Jersey, U.S.A. The company has a capital of 100,000 dollars, and will construct, maintain, and operate telephone lines in the United States of Colombia and Venezuela. The main office is at Longbranch.

ELECTRIC LIGHT AT SALTLEY.—With reference to our note of last week under this head, the manager of the Birmingham and Warwickshire Brush Electric Light Company writes to say that the installation at Messrs. Brown, Marshall and Co.'s works was completed some time since. It consists of 40 Brush lamps, driven by a 16 horse-power Fowler semi-portable engine.

CRYSTAL PALACE EXHIBITION.—The combined Electric and Gas Exhibition was opened at the Crystal Palace on Wednesday last by the Lord Mayor. At present, as usual with exhibitions, things are in a backward state. No doubt, however, exhibitors will push matters forward now, and we shall hope to be able to give a better account of the exhibition in a week or two's time.

EARTH CURRENTS AND SUNSPOTS.—On the 1st of September, 1859, two astronomers, Messrs. Carrington and Hodgson, who were observing a spot on the sun's disc, noticed a star of light break from the spot and move across the sun's surface. On referring to Kew Observatory subsequently they found that at this particular moment the magnet there had recorded a magnetic disturbance.

A HAZY NOTION OF EARTH CURRENTS.—A broker's office in Wall-street, New York, having a leased wire, sent up a message to 195 on the morning of the big electrical storm to know what was the matter with their wire. Chief Operator Bogart replied that the "aurora" was on it. The firm thereupon telegraphed back to have it cleared off immediately, as they wanted to use the wire.—*Operator.*

PATENT DISCLAIMER.—Notice has been given by Mr. St. George Lane-Fox and the Anglo-American Brush Electric Light Corporation of their intention to file a disclaimer of certain parts of Mr. Lane-Fox's patent, dated 9th October, 1878, No. 3,988, which relates to "Improvements in obtaining light by electricity, and in distributing and regulating the electric current for the same." &c.

ELECTRIC LIGHT IN PRINTING WORKS.—A few days since we noticed that the printing works of Messrs. Hazell, Watson, and Viney, at Aylesbury, were to be lighted throughout by the Provincial Brush Electric Light Company. The lights, Brush arc lamps, were started on Tuesday night. The light was very much appreciated by the printers, and they are unanimous in praise of it, preferring it greatly to gas.

ELECTRIC LIGHTING AT LIVERPOOL DOCKS.—The electric light at the new northern docks, which were formally opened by the Prince of Wales in September last year, has given such satisfaction that an order has been given to extend it so as to light another 200 acres of ground. The work is being executed by the Electric Lighting Supply and Fitting Company, of Victoria Mansions, who designed and carried out the original installation.

ELECTRIC LIGHTING FOR CAMBRIDGE.—The Cambridge Improvement Commissioners have been recommended by their Electric Light Committee not to proceed any further in the matter of obtaining a provisional order, but to content themselves with giving instructions to their officials to see that protective clauses are inserted in any order that may be

Digitized by Google

granted to the Provincial Brush Electric Light Company to supply electricity and light in that town.

Electric Lighting at Manchester.—The Manchester Royal Exchange was illuminated on the night of the 1st December for the first time by the British Electric Light Company, who have secured the contract, with 10 automatic Brockie arc lights of 3,000 candle-power each and 400 British incandescent lamps of 15 candle-power each. The light attracted a great many sightseers and was universally admired. The arc lights will ultimately be increased to 17.

Electric Lighting and Fire Insurance Companies.—The offices of the Eastern Electric Light and Power Company and the Indian and Oriental Electrical Storage and Works Company at Winchester House, Old Broad-street, E.C., have for some time past been lighted by incandescent lamps fed by Sellon-Volckmar accumulators. We are informed that two fire insurance companies have inspected the system, and have duly recognised it in their books without any additional charge being made.

Edinburgh Telephonic Exchange.—During last week upwards of 7,554 calls from subscribers were registered at the switching offices of this Exchange. The week previous showed a total of only 4,992 calls. These facts go to prove the rapid advance which the telephone is now making as a medium of conducting business in the present inclement weather. The luxury thus afforded of carrying on every day work without exposing oneself to the difficulties of locomotion is evidently very largely taken advantage of.

The Detection of Metallic Masses in the Human Body.—We have been favoured by Professor A. Graham Bell with advanced proofs of his paper on this subject, read at the late meeting of the American Association for the Advancement of Science. A short abstract of this paper was given at the time of the meeting. It is possible that we may be able to find the space necessary to give the whole paper, which cannot but be interesting not only to professional electricians, but to surgeons and soldiers.

Extension of the Telegraph in the North.—A meeting of farmers was held on Wednesday week at Fortingall, Perthshire, in connection with the establishment of a telegraph line between Aberfeldy, Fortingall, and the district of Glenlyon. Sir Donald Currie, M.P., was present, and explained the arrangements which he had made with the Government in the matter. The meeting decided to take steps to complete the guarantee fund, and Sir Donald Currie was authorised to conclude the terms with the Government.

Electric Lighting in Newcastle-on-Tyne.—Messrs. James Coxon and Co., drapers, of Newcastle-on-Tyne, have successfully introduced incandescent lighting into their shop. Their windows are lighted by Swan lamps of 50 candle-power, and the shops and show rooms by the ordinary Swan lamps of 20 candle-power. The *employés* of this firm have, doubtless, learnt to appreciate the pure atmosphere afforded when incandescent lighting is employed in place of gas. The absence of steamy windows during this cold weather must also be a pleasantly obtrusive fact.

Storing Electricity.—This is the title of an article in this month's *Harper's Magazine*. The writer gives a brief exposition of the storage of energy, utilising the well-worn water analogy for his purpose. He then describes the experiments of Gautherot, Ritter, Grove, and Planté, illustrating Grove's gas battery and Planté's secondary battery. He concludes by a description of Faure's modification of the Planté cell. The more recent labours of Sellon and Volckmar, Sutton, and others are not mentioned. Perhaps some hypercritical electricians may object to the title "Storing Electricity." We have heard it said that electricity cannot be stored, though electrical energy may.

Electric Light on Shipboard.—The United Steamship Company's steamer "Kjobenhavn" has just been lighted with incandescent lamps by the British Electric Light Company. The lamps have been tastefully arranged throughout the ship, and fitted on bronze gilt brackets representing mermaids. The lights have been running now for nearly two months, and have given great satisfaction. One arc light is used on board. It is probable that other vessels of the same line will be lighted by the same system. The British Indian Steam Navigation Company's "Dacca" is to be lighted by means of 108 British incandescent lamps and two arc lamps, supplied and set up by the British Electric Light Company.

Severe Thunderstorm in Orkney.—Reports from Kirkwall, dated December 11, speak of a severe thunderstorm which passed over the Orkneys on the previous night, severely wounding five people and killing four cattle. The storm came on shortly before six o'clock, and continued for some time. As Mr. William Hepburn, wife, and family were sitting at the fire a flash came down the chimney, and struck the whole five. Mrs. Hepburn was struck behind the ear, her ear being laid open on her cheek; her husband was severely struck from the abdomen down. Miss Hepburn, her brother, who was married, and his little boy were also struck. Some of them had their clothes burnt. Grave fears are entertained for the recovery of the old people.

Underground Wires in America.—The Brooks Telegraph Company of New York intend to grant licenses to subcompanies to lay underground wires in the different cities of America. It is authoritatively stated that the Western Union Company will lease from these companies such wires as they need, instead of laying a system for themselves. The Western Union Company cannot afford, it is said, to change from the overhead system and pay dividends at the same time unless the expense is thus divided with all others interested. Such a license has already been granted to certain gentlemen to lay 5,000 miles of wire in Philadelphia, underground, within two years, provided they obtain proper facilities for doing so from City Councils, and, if laid, the wires will be open to the use of any corporation willing to pay rental for them.

Electric Lighting at Danzig.—A correspondent writes:—"A number of experiments were made yesterday (Dec. 5) at the office of Herr Von Assman, who is the chief engineer of the marine works at the German Imperial Docks here (Danzig). The intensity of various gas burners was measured by means of a Bunsen photometer. The ordinary Danzig gas burner was found to give only about six candles. The Edison light, when measured, gave a light equal to 17 standard candles. An opal shade was then put over the light, and the intensity was reduced to about eight candles, thus showing a loss of about 55 per cent., when a ground glass globe is used the loss is about 20 per cent. The Edison light is used here to light up the machine works, as they work till ten o'clock every evening. A and B lamps are used, and the workmen are well satisfied with the light."

Electric Light on the "Himalaya."—The first complete installation of incandescent lamps in the Royal Navy has been just submitted for trial on board H.M. troopship "Himalaya" at Devonport Dockyard, where, for nearly two years, she has been undergoing complete renovation. A contractor's run was made on Wednesday last before the officials of the Admiralty, when extremely satisfactory results were obtained both as to working of machines and engines, which are of the Siemens-Brotherhood type, and as to the illumina-

Digitized by Google

tion afforded. The installation has been effected by the Swan United Electric Light Company, and about 170 lamps of 20 candles each and 60 lamps of 10 candles each have been employed, which are destined entirely to replace all other means of lighting. The utmost care has been taken to ensure perfect insulation of the leads and durability and strength in the fittings. The work has been carried out by Mr. J. F. Albright, engineer to the company.

Summer Telegraph Offices in Germany.—The Berlin correspondent of *The Times*, telegraphing on Wednesday, says:—"Some interesting statistics have just been issued as to the experiment tried this year of establishing summer post and telegraph offices on mountain peaks, and other remote and solitary spots much visited by tourists. The result has been such as to encourage a repetition of the practice. In all, 103,585 letters and 8,064 telegrams were thus forwarded; more than 23,000 of the former alone having been despatched from the Bastei, a lofty precipice in the Saxon Switzerland. From the Wartburg, in Thuringia, 20,000 letters have been sent, and an equal number from the Schneekoppe, in the Giant Mountains, from the Brocken, in the Harz, 16,000, and so on. From the Brocken and the Schneekoppe were sent 1,576 and 1,279 telegrams respectively. The inventiveness of Dr. Stephan, the Postmaster-General of the Empire, is notorious. Several bodies of officials from St. Martin's-le-Grand have come over to Berlin within the last year or two to study the working of the General Post Office, an institution in which the most captious foreigner could find little to criticise."

Protection against Lightning.—The Pic du Midi Observatory, recently established in the Pyrenees, is of necessity greatly exposed to thunderstorms. In consequence considerable care has been taken to protect it against the effects of lightning. Two lightning conductors about 8ft. high have been fixed at the two ends of the house, and connected together by an iron armature, as also with all the ironwork of the building, and with thistle-headed metallic spikes having six points at the angles of the roof and on the shed. It was found advantageous to make the points truncated cones, instead of sharp; they are of gold-plated copper, with tin junctions. These points remain intact, while sharp ones are damaged. The whole system is connected with two other large conductors, 233ft. apart, on two small eminences a little way from the house, and connected by chains, the one with the Lac d'Ouest, the other with a snowy ravine. The arrangement works perfectly; a hissing sound is often perceptible during thunderstorms, and it seems as though the storm is of diminished intensity at that point. It is said that the telegraph clerk at Bagnères, however, has often to use his lightning conductor to avoid being struck. The observatory is situate at between 9,350 and 9,400 feet above the sea (2,877 metres).

Electric Lighting and Gas.—In the course of a discussion on a recent paper read by Mr. C. J. Woodbury, before the New England (U.S.A.) Cotton Manufacturers' Association, which we have alluded to in another note, Mr. C. W. Lippitt, of Woonsocket, Rhode Island, said that the Globe Mills had been supplied with the electric light, and it was much preferred to gas. For the season of 1881 and 1882 the company had used 117 large lights, running them for 367 hours, at an actual cost of 327dols. 83c. Each lamp supplied four looms with light. These took the place of 220 gas burners, which, burning four feet of gas per hour for 367 hours, cost 710dols. 60c. The saving in favour of electric lights was 382dols. 77c., or an actual saving of 57 per cent. In another mill oil gas is used, and although it can be supplied at a lower cost, its results are not so good as coal gas. The cost of running 220 burners of oil gas for 367 hours is 473dols. 11c., which still leaves a margin of 145dols. 28c., or 31 per cent. in favour of the electric light. Mr. Thomas Livermore, of the Amoskeag Mills, said that they had 5,000 looms lighted with 465 electric lights, which had during the last eight months consumed 37,000 carbons. The average cost of each lamp per hour is 2·89c. He had found that one arc lamp could take the place of twelve gas burners, supplying twelve looms with light.

Continuous Lighting for Sixty-four Hours.—During the recent extraordinary fog the Edison Electric Light Company, recognising the necessity for distributing the light to their customers without intermission, maintained their dynamos in action at Holborn-viaduct for a continuous period of sixty-four hours without stopping. Starting at three o'clock on Saturday afternoon, December 9, the dynamos ran without ceasing during Saturday, Sunday, Monday, and Monday night, stopping at eight o'clock on Tuesday morning, December 12. We do not know of any previous continuous, nor, in fact, any similar running to this. The current was supplied from two large dynamos, which are used alternately, and during this long run the current was switched off from one dynamo on to the other, or back again five times by means of a specially designed switch, which enables this to be done without in the least degree interrupting the lighting. The incandescent lamps in the shops on Holborn-viaduct and in the street were thus maintained during the whole of this time. The company has therefore demonstrated not only their ability to supply electric lighting on a large scale, as they have been doing for the past nine months, during the hours of usual darkness, but to maintain constant electrical pressure in the mains day and night, and to comply completely with the condition of continuity of lighting, which is requisite in order that the problem of distributing electricity for lighting and other purposes may be considered solved.

Dynamos.—On Monday night Professor Sylvanus P. Thompson delivered the second of the Cantor Lectures for the session 1882-3, on Dynamo Electric Machinery, at the hall of the Society of Arts, Adelphi. Sir F. Bramwell occupied the chair. Professor Thompson, dealing with the dynamo in practice, said that the first point to consider was the forms of combination used for producing either constant strength in the current or constant electromotive force in the circuit, with the view of rendering the action of the dynamo purely automatic, so that the removal of lamps from one part of the circuit should not in the least affect any other part. Turning to various points in which theory had been put into practice in different descriptions of dynamo electric machines he commented on the forms of the magnets, the pole pieces, the armatures, and the commutators used. He then pointed out the essential difference between a continuous current machine and an alternate current machine, and the peculiar arrangements of the more interesting types, such as those of Edison, Brush, and Gülcher. The distribution of potentiality on the commutators of dynamos he had particularly examined, and had deduced several important consequences with reference to the construction of armatures and field magnets. He observed that science had now advanced so far that it could point out how machines could be constructed with a full knowledge of what their actual performances would be. The subject of the next and concluding lecture is the dynamo as a motor.

Electric Lighting for the City.—On Thursday week a special meeting of the City Commissioners of Sewers was held at the Guildhall, when Mr. Moore again proposed the

Digitized by Google

rescinding of two resolutions which had been passed at a previous meeting—viz., "That while the Commission is in favour of electric lighting in the abstract, it is advisable to allow all further experiments to be conducted at the risk of the lighting companies, and not at the expense of the ratepayers;" and, secondly, "That the Remembrancer be instructed to appear on the application of the electric lighting companies and secure clauses protecting public and private rights." This was carried by a small majority, and there then arose a discussion as to the standing orders, by which a two-thirds majority is necessary to revoke a previous motion. The chairman, being at issue with the officers of the Commission and the majority of the Court, had at the last meeting vacated the chair; on Thursday week, after consultation with the Lord Mayor and the Recorder, he returned to his position and declared the motion carried. On the motion of Mr. Stoneham it was then resolved "That, considering the vast interests at stake, a select committee be appointed to inquire into the necessary steps to be taken to enable the commission to become the undertakers for the supply of electricity to the whole or any district of the City of London under the provisions of the Electric Lighting Act, 1882, to report forthwith to the Commission, and that in the meantime the Remembrancer be instructed to oppose all other applications."

Siemens's Selenium Photometer.—The following is a description of a photometer constructed by Messrs. Siemens and Halske, of Berlin. A horizontal copper tube, three centimetres in diameter and 15 centimetres long, is mounted on a stand fixed at one end of a horizontal graduated bar. The stand, with the copper tube attached, is movable about a vertical axis, and is provided with a levelling screw. One end of the tube is fitted with a metal diaphragm having a circular aperture in its centre, and the other with a mounting carrying cross wires. This latter can be removed and replaced by a short horn box containing a plate of selenium specially prepared. The plate is protected from the light by a valve, which can be opened by a button outside the tube. At two opposite points of the plate wires are attached, which connect it through a galvanometer to the battery. A. Thomson portable mirror galvanometer is the best. To take observations, the tube is turned towards the light to be measured, which is then centred by means of the cross wires. The diaphragm and the mounting carrying the cross wires are removed, and the latter replaced by the selenium plate. The circuit is completed, and the plate exposed to the light. After reading the deflection of the galvanometer the tube is turned about its vertical axis until it is in line with the graduated rod. A standard candle slides on the rod, and its distance from the plate is adjusted until the galvanometer deflection is the same as before. The intensity of the lights is then proportional to the squares of their respective distances from the plate.

Electric Lighting in London.—At the last meeting of the Islington Vestry, the Electric Lighting Committee were taxed with a want of knowledge of the subject, and one member very sensibly recommended them to educate themselves a little in this particular direction before they reported on the question. The Clerkenwell Vestry have received a report from their Committee of Works relating to the applications of the following companies to supply electricity in their parish, viz.:—The Metropolitan Brush Electric Lighting Company, The Gülcher Electric Lighting Company, The Edison Electric Lighting Company, The "Pilsen," "Joel," and General Electric Lighting Company; Ferranti, Thompson, Ince, and Company (Limited), and The Maxim Weston Electric Light Company. The committee recommended that the consent of the vestry be given to the applications of the Metropolitan Brush Electric Lighting and Power Company, and the Edison Electric Light Company to the Board of Trade for licenses to light the parish for seven years, subject to the vestry being protected in every respect, and that the liabilities of the companies for repairs of roadways after trench work extend to a period of two years from the date of the work being done. The ratepayers of St. Mary, Newington, S.E., held a meeting last week to protest against the proposed application by the Newington Vestry for a license to supply electricity in the parish. At this meeting a resolution was passed appointing a committee of ratepayers to take steps to oppose the application of the vestry. The St. Pancras Vestry have adopted the report of their Electric Lighting Committee, which recommended them to apply for a provisional order.

Electrical Exhibitions.—This was the subject of a paper read by Mr. W. H. Preece, F.R.S., at the Society of Arts on Wednesday night, Mr. Spottiswoode, P.R.S., in the chair. Mr. Preece's paper was a brief summary of the various exhibitions that have been held since the great exhibition of 1851. The applications of electricity occupied but a small corner at any exhibition until that of 1876. This, however, as far as the public was concerned, was a failure. Its title, "the Special Loan Collection of Scientific Apparatus," was against it, the Press decried it, and, in fact, it fell flat. And yet such priceless treasures as were brought together there will never be collected again. The exhibitions at Paris, the Crystal Palace, and Munich were next alluded to, and the progress indicated at each described. Mr. Preece, in referring to the Congress of 1881, held at Paris, took the opportunity of explaining the various electric units in terms that could be understanded of the people, and advocated the adoption of the metric system. The recent fires that have occurred gave him an opportunity of impressing upon his hearers the capability possessed by electricity in combination with wires, thermometers, and electric bells, of indicating automatically at half a dozen different places the first outbreak of a fire. *En passant*, too, he referred to several photographs which had been taken by Herr Von Zeemssen, a celebrated physiologist of Munich, of an individual who had been involuntarily compelled to assume expressions of various emotions by the application of currents of electricity to various nerves of the face. Mr. Preece's graphic and laughable description of these photos seemed to be appreciated by his audience. The paper will be printed in full in the *Journal of the Society of Arts*. We regret that we have no space for anything but this brief notice.

The Electric Lighting Act.—In the course of his recent presidential address to the Royal Society, Mr. Spottiswoode said that the "Act would have a scientific influence, perhaps, not contemplated by its original promoters. Under this Act, for the first time in the history of the world, energy would come under the grasp of the law, would become the subject of commercial contracts, and be bought and sold as a commodity of everyday use. It was, in fact, far from improbable that the public supply of electricity would be reckoned and charged for in terms of energy itself. But whether this be literally the case or not, a measurement of energy must lie at the root of every scale of charge. Since the Act allowed no restriction to be placed upon the use of the electricity so supplied, it followed that it might be used, and undoubtedly would be used, at the pleasure and convenience of the customer, either for lighting, or for heating, or for

Digitized by Google

mechanical, or for chemical purposes. This being so, it was clear that the public must by this process become, practically at least, familiar with the various modes of the transformation of force; and the Act in question might, from this point of view, have been entitled 'An Act for the Better Appreciation of the Transformation of Force.' It had been said, and perhaps with truth, that the electric light would be the light of the rich rather than that of the poor. But in more ways than one electricity might now become the poor man's friend. The advantages in avoidance of heat and of vitiated atmosphere in workshops and factories had often been pointed out, and might ultimately become an important factor in the physical growth and prosperity of our population. But besides this, when electricity was literally brought to our doors, it would become possible, by converting it into motive power of limited extent, to revive some of the small industries which during the last half century have been crushed by the great manufacturing establishments of the country. There were operations capable of being carried out by the wives and families of workmen; there were works of small extent which could be performed more advantageously in a small establishment than in a large one, and it could hardly fail to be a gain to the community if this new departure should give fresh opportunities for the development of our industry in these directions."

Legal.—The case of Phillips *v.* the Great Western Electric Light and Power Company came before Mr. Justice Chitty last week. This was an application by a shareholder of ten shares in the company for the rectification of the register of the company by striking out his name from the list of shareholders. The company was incorporated in March, 1882, with a capital of £125,000, divided into 25,000 shares of £5 each. It was stated in the prospectus that the company had secured a concession from the Anglo-American Brush Electric Light Corporation, under which the exclusive right of use or sale of their dynamo machines and arc lamps, together with an exclusive license to use or sell the Lane-Fox incandescent lamp, was secured to the company for a considerable part of the West of England and South Wales. It was stated on behalf of the applicant that on the 20th of July, 1881, Mr. St. George Lane-Fox assigned to the British Electric Light Company the exclusive right of using and granting licenses to use his inventions in Great Britain and Ireland, and that on the 29th of July, 1881, Mr. St. George Lane-Fox executed a similar assignment to the Anglo-American Brush Electric Light Corporation, subject, nevertheless, to the previous assignment of the 20th of July, 1881. It was contended that the statement in the prospectus with respect to the exclusive right of the company to use or sell the Lane-Fox incandescent lamp in the district named was incorrect. The applicant, without alleging any *mala fides* on the part of the company's promoters and directors, submitted that he was induced by what was, in fact, a false representation to subscribe for the shares in question. — Mr. Waller, Q.C., and Mr. F. T. Procter appeared in support of the application.—Mr. Romer, Q.C., and Mr. Phipson Beale, on behalf of the company, opposed the application on the ground that the mis-statement, if a mis-statement at all, was not material, since the Lane-Fox lamp was the least valuable of the inventions purported to have been conceded to the company by the Anglo-American Corporation.—Mr. Justice Chitty said that, although there was no bad faith, but only some carelessness, imputed to the framers of the prospectus, yet it was plain to an ordinary mind that there had been a mis-statement which was material and calculated to mislead the applicant. His lordship also, without expressing any opinion himself one way or the other as to the value of the Lane-Fox invention, thought that it was not competent for persons who had issued a prospectus which, from beginning to end, had recommended as one of its leading attractions this particular invention to afterwards say, for the purpose of upholding their prospectus, that the invention was of little or no value, and, therefore, not a chief attraction in the prospectus. The application must, therefore, be granted with costs, and the sums paid in respect of the shares returned to the applicant by the company.

Electric Lighting in Mills.—The following is extracted from an account of his inspection of various mills using electric lights, given by Mr. C. J. Woodbury, who is connected with an American insurance company, to the New England Cotton Manufacturers' Association. He first called attention "to the superiority of the electric light over gas, in that it did not vitiate the atmosphere and so impair the health of the workmen. An instance was cited of a basement story of a mill 400ft. by 65ft. and 15ft. high, and containing 456 looms, which was lighted by 457 4-ft. gas burners. It was stated that when the burners were in use the temperature of the room increased 25 degrees in an hour. The gas burners were then replaced by 35 electric lights, and no increase of temperature is noticed. Another advantage of the electric light in mill work is the facility which it affords the operators to distinguish colours and different tints of the same colour at night. In some departments this is of the greatest importance, as the inability to distinguish colours would limit the work to the hours of sunlight. Moreover, it is claimed that the improved illumination obtained by electricity effects a saving, because the proportion of damaged goods usually made when the mill is poorly lighted is thereby diminished. The majority of mills are lighted with gas made by the destructive distillation of petroleum, and of about 80 candle-power, which is generally reduced to 60 candle-power by mixing air with it. The annual cost of oil gas per burner is from 75c. to 1·00dol. In all these estimates interest at six per cent. forms one item in cost. One large corporation, with exceptional privileges, makes its coal gas at an annual cost of 69c. per burner. Another corporation, inland, makes its gas at an annual cost of 1·79dol. per burner. Of two large mills in the same city, manufacturing similar goods, the more modern one makes oil gas at an annual cost of 79c. per burner, while the older one buys coal gas at 2·65dols. per burner. The longer time light is required, the average cost is lessened, because with the addition of operating expenses, the interest on plant, being a fixed amount, becomes a smaller proportion of the whole cost. A dark mill, that is, one of which the interior walls are not whitened, requires about twice the number of lights that are sufficient in a white mill, and uses light about 100 hours a year more than a white mill. The cost of arc lights in several steam mills running 400 hours per year is 6⅔c. per hour, of which 1½c. is for carbons and 5c. for attendance, coal, depreciation, and interest. In a weave room, on very fine work, 24 arc lights replaced 292 6-foot gas burners, which consume 1,752 feet per hour, so one arc light represents the consumption of 73 feet of gas per hour. A careful estimate shows these arc lights to be costing 6½c. an hour, so this arc lighting system represents gas at 89c. per 1,000. A similar estimate in another mill gives the annual cost of gas 21·88dols, and electricity at 11·25dols., or equal to gas at 90c. per 1,000." We may remark that these figures would be much more valuable if they mentioned what system of electric lighting was employed.

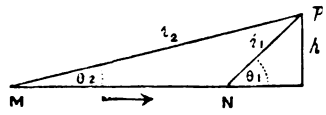
MAGNETIC FORCE OF RETURN CURRENT THROUGH THE EARTH, AND ALLIED MATTER.

BY OLIVER HEAVISIDE.

The magnetic force of a current system can only be completely known when the current is everywhere known (or equivalent information must be given), and no part of the system can in strictness be neglected. If, then, the circuit of a linear current is completed through the earth, the earth-current itself contributes something to the magnetic force. This, as will be seen, is quite a small matter; yet its investigation is both interesting in itself as affording an excellent example of the relations between current, its vector-potential and magnetic force, and on account of a current-sheet analogue that presents itself.

The magnetic force of a straight current C at distance h from the axis is $\frac{2C}{h}$ perpendicular to the plane containing h and the axis, provided the point chosen be not near the ends of the wire, nor at a very great distance from the wire. But in our present case we shall require the correction for the ends.

Let M N be the wire, the current C going from M to N; and let P be any point distant r_1 from N and r_2 from M and



h from the axis or its continuation. Let θ_1 and θ_2 be the angles r_1 and r_2 make with the axis. Then the magnetic force at P of the wire current alone (vector-potential of curl of current) is

$$\frac{C}{h}(\cos\theta_2 - \cos\theta_1) = \frac{C}{h}(1 - \cos\theta_1) - \frac{C}{h}(1 - \cos\theta_2) \quad \ldots \quad (1)$$

and its direction is perpendicular to r_1, r_2, and h. If the diagram has not been perverted, the direction at P will be upwards from the paper. When the point P is near the wire, but not near the ends, we may put $\theta_1 = +\pi$, $\theta_2 = 0$, and we obtain the former expression $\frac{2C}{h}$. Confining ourselves to the neighbourhood of one end, say N, we may put $\theta_2 = 0$; consequently the magnetic force is

$$\frac{C}{h}(1 - \cos\theta_1) \quad . \quad . \quad . \quad . \quad . \quad (2).$$

Just over the end, $\theta_1 = \frac{\pi}{2}$, and the force is $\frac{C}{h}$ only; and along the continuation of the wire it is 0.

Now, although the expression (1) is the vector-potential of the curl of the wire current only, it is also the complete magnetic force of the closed circuit which would be formed by immersing the ends of the wire in an infinitely extended conducting medium, so that the current C leaving N spread out uniformly, the tubes of flow afterwards bending round and finally converging uniformly to M. *I.e.*, (1) expresses the magnetic force of the straight current, together with a radial current of strength $\frac{C}{4\pi r_1^2}$ parallel to r_1, and of another of strength $-\frac{C}{4\pi r_2^2}$ parallel to r_2.

For consider the first mentioned radial current. Its three components are

$$u = \frac{Cx}{4\pi r_1^3}; \qquad v = \frac{Cy}{4\pi r_1^3}; \qquad w = \frac{Cz}{4\pi r_1^3};$$

if x, y, z are the components of r_1. The x-component of the curl is, (Theorem II., p. 56)

$$\frac{dw}{dy} - \frac{dv}{dz} = \frac{C}{4\pi}\left\{z\frac{d}{dy}\left(\frac{1}{r^3}\right) - y\frac{d}{dz}\left(\frac{1}{r^3}\right)\right\} = 0;$$

and similarly the y and z components are *nil*, therefore the curl of the radial current is *nil*, and likewise the vector-potential of the curl; hence the radial currents contribute nothing to the magnetic force.

[Any radial function has no curl. For, let $f(r)$ parallel to r be such a function, then $f(r)\frac{x}{r}, f(r)\frac{y}{r}, f(r)\frac{z}{r}$, are its components, and the x-component of its curl is

$$f(r)\left(z\frac{dr^{-1}}{dy} - y\frac{dr^{-1}}{dz}\right) + \frac{1}{r}f'(r)\left(z\frac{dr}{dy} - y\frac{dr}{dz}\right) = 0.\Big]$$

But in the actual case of return through earth the diffusion is one-sided only. The curl of current within the earth is *nil*, as before, but since there is now a bounding surface, and consequently surface-curl, the earth current does give rise to magnetic force. If D is the surface curl, its strength is $\frac{C}{2\pi a^2}$ at distance a from the electrode (meaning the point N on the earth's surface), and its direction is perpendicular to a (see p. 8). *I.e.*, the lines of surface-curl are concentric circles drawn upon the earth's surface, centred at the electrode. The vector-potential of D is the magnetic force of the earth current. Calling it B, since D has no vertical component, neither has B; and evidently B has the same value and direction at two corresponding points above and below the surface (one being the image of the other). From the symmetry about the electrode, we see that the lines of magnetic force are circles in planes parallel to the earth's surface, and centred upon the vertical axis through the electrode. As we recede from the latter, the strength of force rapidly diminishes.

The strength of force may be determined indirectly thus:—Let us denote by C_1 the uniformly-diffused radial current of strength $\frac{C}{4\pi r_1^2}$. If to this we add another radial current of the same strength everywhere as C_1, but directed *to* the electrode above the earth, and from it below, which system we may call C_2, their sum will be 0 above and $\frac{C}{2\pi r_1^2}$ below the earth's surface, and this is the real earth current.

Now, if we take the curl of the expression (2), we shall obtain the current C_1 (disregarding the wire current). We may do this by using the components of (2); or, more simply, thus:—The line integral of (2) round the circle of radius h perpendicular to the axis is

$$\frac{C}{h}(1 - \cos\theta_1) \times 2\pi h = \frac{C}{r_1^2} \cdot 2\pi r_1^2 (1 - \cos\theta_1).$$

This is $4\pi \times$ current through the circle (see p. 5). Now, $2\pi r_1^2(1 - \cos\theta_1)$ is the area of the portion of spherical surface with centre at N and radius r_1 bounded by the circle; consequently $\frac{C}{4\pi r_1^2}$ is the current-density.

Now, the curl of the magnetic force B of earth-current must be $4\pi \times C_2$. But C_2 and C_1 are identical within the earth, therefore B must be of the same form as (2), *i.e.*,

$$B = \frac{C}{h_1}(1 - \cos\phi) \quad . \quad . \quad . \quad . \quad (3),$$

where h_1 is the distance of the point considered from the axis of the earth-current (not of the wire), *i.e.*, the vertical through the electrode, and ϕ the angle between r_1 and this axis (positive direction) downwards. But, above the earth, C_2 and C_1 are oppositely directed; B must, therefore, be so changed that its curl becomes reversed. This may be done by making

$$B = \frac{C}{h_1}(1 + \cos\phi) \quad . \quad . \quad . \quad . \quad (4).$$

We may express (3) and (4) in one formula, thus:—

$$B = \frac{C}{h_1}(1 - \sqrt{\cos^2\phi}) \quad . \quad . \quad . \quad . \quad (5).$$

i.e., we take the numerical value of $\cos\phi$, whether it is $+$ or $-$.

Digitized by Google

The actual magnetic force near the electrode is the vector-sum of (2) and (δ). One case may be noticed, where it simplifies. Let $\theta_1 = \phi$ and $h = h_1$ so that the wire enters the earth perpendicularly. Above the earth, we shall have

$$B = \frac{C}{h}(1 - \cos\theta_1) + \frac{C}{h}(1 + \cos\theta_1) = \frac{2C}{h},$$

perpendicular to r_1 and h. And below the surface,

$$B = \frac{C}{h}(1 - \cos\theta_1) + \frac{C}{h}(1 - \cos\theta_1) = \frac{2C}{h}(1 - \cos\theta_1).$$

We may now examine an interesting analogy which has a realisable existence, and may serve to clarify the above. Suppose that we have an infinite thin plane sheet of conducting material; choosing any point N in it for origin, let currents circulate in the sheet in circles about N, the strength being $\frac{C}{2\pi a^2}$ at distance a. If when we view the sheet we see the current circulate right-handedly, we see the negative side, and the + direction of the axis of the currents is from the negative to the positive side of the sheet. Now we have found the vector-potential of this current-system; it is expressed by equation (5), using the same notation as regards h_1 and ϕ. The magnetic force is the curl of (5), and is therefore radial, of strength $\frac{C}{r^2}$ on the − side and $-\frac{C}{r^2}$ on the − side. *I.e.*, the magnetic force of the current-sheet is that which would be produced by a magnetic pole of strength C placed at the origin, with this difference, that it acts as a + pole on the + side and as a − pole on the − side of the sheet, as shown in the diagram annexed. (We have here an

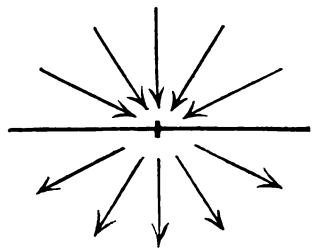


illustration of the continuity of the normal and discontinuity of the tangential component of magnetic force referred to in p. 33.)

How produce such a current system? Easily enough; permanently, if we had a sheet of infinite conductivity, transiently and imperfectly with a resisting sheet.

It is a cardinal truth in electrostatics that, when an uncharged insulated conductor is placed in an electric field, it becomes charged in such a manner that the force due to its charge exactly annuls that of the undisturbed field for all internal points, so that there is no electric force within the conductor.

Now, there is a corresponding theorem in electro-magnetics. If a closed sheet of infinite conductivity, having no current in it initially, be placed in a magnetic field, a system of currents will be set up in it of such a nature that the magnetic force due to it exactly annuls that of the undisturbed field within the space bounded by the sheet (or, in the case of an infinite sheet, on the further side from the source of magnetic force). Practically, with a resisting sheet, bringing it rapidly into the magnetic field, or, bringing the field to it, would set up the currents approximately, to be quickly killed by the resistance.

Let us then bring a magnetic pole of strength C suddenly to the origin on the + side. Its force is $\frac{C}{r^2}$ radial, on both sides. But there must be no force on the − side, by the above-mentioned theorem. So the magnetic force of the currents set up will be $-\frac{C}{r^2}$ radial on the − side, and on account of the reversal of the tangential component in passing through the sheet, it must be $+\frac{C}{r^2}$ radial on the + side. But since this field is exactly that produced by the distribution of current assumed before, it must be the current set up by the magnetic pole. The actual magnetic force of pole and current together is 0 on the − and $\frac{2C}{r_1^2}$ on the + side, *i.e.*, similar to the distribution of the current entering earth.

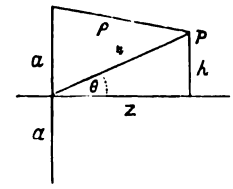
A magnetic shell which would produce the same field of force would have strength

$$\int_a^\infty \frac{C\,da}{2\pi a^2} = \frac{C}{2\pi a}.$$

This would be the magnetic moment per unit area.

[Test. Curl of intensity of magnetisation = vol. density of equivalent current. Taking the curl of $\frac{C}{2\pi r} \parallel z$, we find x-component $= -\frac{Cy}{2\pi r^3}$; y-component $= \frac{Cx}{2\pi r^3}$; z-component $= 0$. Resultant, $\frac{C}{2\pi r^2} \perp r$ in plane of sheet.]

As the mode of obtaining equation (5) may be considered obscure, it is desirable to check it by direct integration. It comes to the same thing if we find the vector-potential of the current sheet, current $= \frac{C}{2\pi a^2} \perp a$ at distance a from the origin. Let the sheet be in the plane of x y, and measure z positive from the origin on the + side. Let θ be the angle between r the radius-vector of a point P and z, and x, y, z the co-ordinates of P. First find the vector-potential at P of a circular unit-current of radius a. If h is parallel to the x-axis,



the y-components of the current contribute nothing to the vector-potential; the x-component of the element $a\,d\phi$ (measuring ϕ from the x-axis) is $a \sin\phi\, d\phi$; therefore the vector-potential of the circular unit current is

$$\int_0^{2\pi} \frac{1}{\rho} a \sin\phi\, d\phi \quad \ldots\ldots \quad (6).$$

Where ρ is the distance of P from the element $a\,d\phi$, and is given by

$$\rho^2 = r^2 + a^2 - 2ha\sin\phi.$$

The complete vector-potential of the current-sheet is therefore

$$B = \frac{C}{2\pi}\int_0^\infty \int_0^{2\pi} \frac{1}{a\rho} \sin\phi\, da\, d\phi \quad . \quad (7).$$

Let the limits for a be first a and ∞; a to be afterwards made 0. Then, by integration to a we find

$$B = -\frac{C}{2\pi}\int_0^{2\pi} \frac{1}{r} \sin\phi \log\left(\frac{1}{r} - \frac{h\sin\phi}{r^2}\right) d\phi$$

$$+ \frac{C}{2\pi}\int_0^{2\pi} \frac{1}{r} \sin\phi \log\left(\frac{1}{a} - \frac{h\sin\phi}{r^2} + \frac{\rho}{ar}\right) d\phi = B_1 + B_2 \text{ say.}$$

Now the definite integral

$$\frac{1}{2\pi}\int_0^{2\pi} \sin\phi \log(m + n\sin\phi)\, d\phi = \frac{m - (m^2 - n^2)^{\frac{1}{2}}}{n};$$

consequently, $$B_1 = C\frac{r - (r^2 - h^2)^{\frac{1}{2}}}{rh}.$$

Now, in the second integral B_2, a has to be ultimately 0. The quantity under the radical, *i.e.*, in the expression for ρ,

Digitized by Google

therefore varies infinitely little from r^2, whilst ϕ goes from 0 to 2π. The quantity to be integrated then becomes of the same form as in B_1; but also, we shall have $m = \infty$, $\therefore B_2 = 0$. Thus

$$B = B_1 = C\frac{r - (r^2 - h^2)^{\frac{1}{2}}}{rh} = C\frac{1 - \sqrt{\cos^2\theta}}{h} \quad . \quad (8)$$

is the complete solution, showing that (5) is correct.

The integral (6) does not admit of finite expression, being elliptic (see Maxwell's "Electricity," Vol. II., Art. 701). Its expansion in spherical harmonics will furnish us with another proof of (8). Substitute for the circular unit current of radius a an equivalent plane magnetic shell of unit strength, so that there is magnetism of unit density on its + and of density -1 in its $-$ face. Let V be the potential of the + magnetism, then $+\frac{dV}{dy}$ and $-\frac{dV}{dx}$ will be the x and y components of the vector-potential. First find V for a point upon the axis, then

$$V = \int_0^a\int_0^{2\pi} \frac{a\,da\,d\phi}{\sqrt{a^2 + z^2}} = 2\pi\left\{(a^2 + z^2)^{\frac{1}{2}} - z\right\}$$

Expand this by the Binomial Theorem in powers of z, and call it V_1 when $z < a$ and V_2 when $z > a$. Then

$$V_1 = -2\pi z + 2\pi a\left(1 + \frac{1}{2}\frac{z^2}{a^2} - \frac{1}{2.4}\frac{z^4}{a^4} + \frac{1.3}{2.4.6}\frac{z^6}{a^6} - \ldots\right)$$

$$V_2 = 2\pi z\left(\frac{1}{2}\frac{a^2}{z^2} - \frac{1}{2.4}\frac{a^4}{z^4} + \frac{1.3}{2.4.6}\frac{a^6}{z^6} - \ldots\right)$$

Next let point be not on the axis; we may generalise the last by writing rQ_1 for z, r^2Q_2 for z^2, etc., in V_1, and $\frac{Q_n}{r^{n+1}}$ for $\frac{1}{z^{n+1}}$ in V_2, where the axis of Q's is along z. Thus,

$$V_1 = 2\pi a\left(1 - \frac{r}{a}Q_1 + \frac{1}{2}\frac{r^2}{a^2}Q_2 - \frac{1}{2.4}\frac{r^4}{a^4}Q_4 + \ldots\right)$$

$$V_2 = 2\pi a\left(\frac{1}{2}\frac{a}{r}Q_0 - \frac{1}{2.4}\frac{a^3}{r^3}Q_2 + \frac{1.3}{2.4.6}\frac{a^5}{r^5}Q_4 - \ldots\right)$$

Consequently the x-component of the vector-potential is

$$\frac{dV_1}{dy} = 2\pi\frac{y}{a}\left(-\frac{1}{2} + \frac{1}{2.4}\frac{r^2}{a^2}\cdot\frac{dQ_3}{d\mu} - \frac{1.3}{2.4.6}\frac{r^4}{a^4}\frac{dQ_5}{d\mu} + \ldots\right)$$

or

$$\frac{dV_2}{dy} = 2\pi a^2\frac{y}{r^3}\left(-\frac{1}{2} + \frac{1}{2.4}\frac{a^2}{r^2}\frac{dQ_3}{d\mu} - \frac{1.3}{2.4.6}\frac{a^4}{r^4}\frac{dQ_5}{d\mu} + \ldots\right)$$

according as r is $<$ or $>$ a. In getting the last expressions we have made use of the relations

$$\frac{d}{dy}(r^nQ_n) = -y\,r^{n-2}\frac{dQ_{n-1}}{d\mu},$$

$$\frac{d}{dy}\left(\frac{Q_n}{r^{n+1}}\right) = -\frac{y}{r^{n+3}}\frac{dQ_{n+1}}{d\mu},$$

where $\mu = \cos\theta$. The y-component is got by writing $-x$ for y, so that the actual magnitude of the vector-potential of the circular unit current is

$$\left.\begin{aligned}\frac{2\pi h}{a}\left(+\frac{1}{2} - \frac{1}{2.4}\frac{r^2}{a^2}\frac{dQ_3}{d\mu} + \frac{1.3}{2.4.6}\cdot\frac{r^4}{a^4}\frac{dQ_5}{d\mu} - \ldots\right) &= A_1 \text{ say}\\ \text{or}\\ 2\pi a^2\cdot\frac{h}{r^3}\left(+\frac{1}{2} - \frac{1}{2.4}\frac{a^2}{r^2}\frac{dQ_3}{d\mu} + \frac{1.3}{2.4.6}\frac{a^4}{r^4}\frac{dQ_5}{d\mu} - \ldots\right) &= A_2 \text{ say}\end{aligned}\right\} \quad (9)$$

Now, since the current strength in the sheet is $\frac{C}{2\pi a^2}$, the complete vector-potential is

$$B = C\int_r^\infty \frac{A_1\,da}{2\pi a^2} + C\int_0^r \frac{A_2\,da}{2\pi a^2}.$$

Substituting the above values of A_1 and A_2, and performing the integrations,

$$\begin{aligned}B &= \frac{Ch}{r^2}\left(+\frac{1}{2}\cdot\frac{1}{2} - \frac{1}{2.4}\cdot\frac{1}{4}Q'_3 + \frac{1.3}{2.4.6}\cdot\frac{1}{6}Q'_5 - \ldots\right)\\ &+ \frac{Ch}{r^2}\left(+\frac{1}{2} - \frac{1}{2.4}\cdot\frac{1}{3}Q'_3 + \frac{1.3}{2.4.6}\cdot\frac{1}{5}Q'_5 - \ldots\right)\\ &= \frac{Ch}{r^2}\left(\frac{3}{4} - \frac{7}{3.4}\cdot\frac{1}{2.4}Q'_3 + \frac{11}{5.6}\cdot\frac{1.3}{2.4.6}Q'_5 - \ldots\right) \quad (10)\end{aligned}$$

where Q'_n is written for $\frac{dQ_n}{d\mu}$.

We must now prove that (10) is the expansion of (8). Any function F of μ may be expanded in $\frac{dQ_n}{d\mu}$'s or Q''s; thus

$$F = F_1Q'_1 + F_2Q'_2 + \ldots$$

and the value of any co-efficient F_n is given by

$$F_n = \frac{2n+1}{2n(n+1)}\int_{-1}^{1} F(1-\mu^2)\,Q'_n\,d\mu.$$

Now in the present case B in (8) is

$$B = \frac{C}{h}(1 - \sqrt{\mu^2}) = \frac{C}{r}\cdot\frac{1 - \sqrt{\mu^2}}{\sin\theta},$$

and $1 - \sqrt{\mu^2}$ is such a function of μ,

$$\text{that } F\left(\frac{\pi}{2} + \alpha\right) = F\left(\frac{\pi}{2} - \alpha\right).$$

Also Q'_n is an even function of μ when n is odd, and an odd function when n is even. Therefore, since from $\theta = 0$ to $\theta = \frac{\pi}{2}$ we have

$$B = \frac{C}{r}\frac{1-\mu}{\sin\theta} = \frac{C}{r}\frac{\sin\theta}{1+\mu}$$

if we expand $\frac{1}{1+\mu}$ in odd Q''s between $\mu = 0$ and $\mu = 1$, the same expression resulting will give the proper value between $\mu = -1$ and $\mu = 0$. So we shall have

$$B = \frac{C\sin\theta}{r}\cdot\frac{1}{1+\mu} = \frac{C\sin\theta}{r}(F_1Q'_1 + F_3Q'_3 + \ldots)$$

where $$F_n = \frac{2n+1}{2n(n+1)}\int_0^1 (1-\mu)\,Q'_n\,d\mu,$$

and the limits being halved, the outer factor has been doubled, and only odd values of n are taken. Carrying this out, we shall obtain the expression for B in (10).

STUDENTS' COLUMN.—We regret that the pressure on our space compels us to leave over our Students' Column until next week.

TELEGRAPH POLES IN WASHINGTON.—The District Commissioners at Washington have decided not to allow any more telegraph poles to be erected in that city unless it can be proved that the public interests require them. It has been further decided that at the earliest possible moment the telegraph companies shall be required to lay their wires underground. For this reason an application made by the Baltimore and Ohio Telegraph Company to erect a line of telegraph poles has been refused.

THE (ELECTRIC) CONDUCTIVE AND INDUCTIVE CIRCUITS GEOMETRICALLY ILLUSTRATED.

BY F. C. WEBB, M.I.C.E.

(CONTINUED FROM PAGE 32.)

If the resistance of the line, or external resistance, is increased from, say B A to B D (Fig. 30), and we wish to obtain the same current as before, then by drawing from D a line parallel to A E until it cuts B E, produced at F, and dropping F H perpendicular to axis, we get B H as the resistance of the battery in terms of B C, and F H as the electromotive force, in terms of C E.

If we have a given number of elements, it is desirable sometimes to know the best way of arranging them with any given external resistance, so as to obtain the maximum current in the circuit. The following well-known problem proves that the best way of grouping them is so that their resistance, if possible, should equal the resistance of the external conductor.

If a single pair of elements be cut into m elements, and these new elements preserving the same distance as before between each positive and negative element be placed in series, it is evident that the electromotive force will be increased m times, but as regards the resistance of the new arrangement, as the plates are m times smaller than the large pair, each pair must have m times the resistance of the large pair, and as there are now m times the number of pairs the total resistance of the battery now formed is $m \times m$ times, or m^2 times the resistance of the large pair.

Thus, if we cut the large pair in two and put them in series, we have twice the electromotive force, but four times

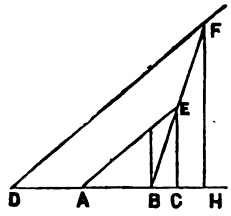

FIG. 30.

the resistance; or, if we cut the large plates in three, we shall have three times the E.F., and nine times the resistance; and, if in four, we shall get four times the E.F. of the large pair, but sixteen times the resistance, and so on.

If, now, we take as abscissæ of a curve these resistances, 1, 4, 9, 16, 25, &c., and as ordinates the electromotive forces, 1, 2, 3, 4, 5, &c., we see that the ordinates are as the square roots of the abscissæ, and the curve is, therefore, a parabol, a, as shown in Fig. 31. If we produce the axis A B, and take any length, A T, as an external resistance, and we now draw a line from T to any part of the curve, say to the point D over F, then the current in this arrangement of 16 elements will be proportional to the steepness of the line of potential T D, or, in fact, to $\frac{D F}{T F}$. But it is evident that the steepest line that can be drawn from T to the curve (that is, the line which, drawn from T, makes the greatest angle with the axis) will be the line which only touches it as a *tangent* as T K, which touches the curve as a tangent at E. The arrangement which gives the ordinate G E is, therefore, the arrangement which gives the maximum current with the external resistance T A in circuit. But it is proved in conic sections (Prop. IV., Cor. 2) that the subtangent A G is equal to A T. But A G is the resistance of the battery in the arrangement amongst them all, which gives the maximum current with A T as external resistance, and this is equal to the external resistance. The same can be proved, whatever length we take A T. Therefore, the best arrangement for cutting up any given surface of plates into is such that the resistance of the series formed shall equal the resistance of the external resistance. If we take any other series we shall find that there is always *another* arrangement which will give exactly the same current. Thus the dotted line drawn from T through D cuts the curve at H, showing that, with the external resistance T A, the series of four plates gives just the same current as the primitive single pair does. Thus, if A T equals four times the resistance of the single pair, then we have for current in the circuit, in figures, $\frac{1}{5}$, and for the current with the four plates $\frac{4}{4+16} = \frac{4}{20} = \frac{1}{5}$, *i.e.*, exactly the same current as with the single pair. In the same way with any external resistance, if we draw a line *cutting* the curve at all it will cut in two places, and we get two points of cutting, each of which will give, by the arrangement of plates it represents, exactly the same current.

The following various groupings of 104 elements will illustrate to the student this problem of the arrangement for maximum current in actual figures. Suppose the 104 elements to be each 1 volt E.M.F., and 1 ohm resistance, and let the external resistance be 4 ohms. Then, if we group all the elements in series, we get

$$\frac{104 \cdot}{104 + 4} = \frac{104 \text{ volts}}{108 \text{ ohms}} = \text{current of } 0{\cdot}96 \text{ ampere.}$$

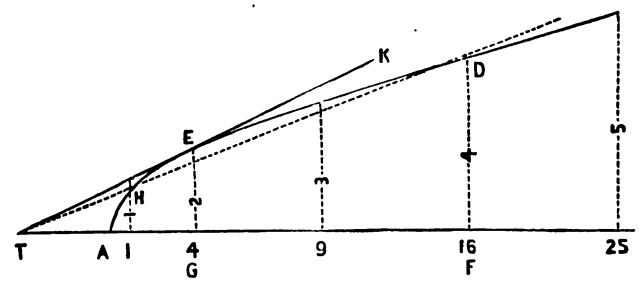

FIG. 31.

If, now, we arrange the battery in two rows of 52 elements each, we get

$$\frac{52 \cdot}{26 + 4} = \frac{52 \text{ volts}}{30 \text{ ohms}} = \text{current of } 1{\cdot}73 \text{ ampere.}$$

Now, making four rows of 26 elements, we get

$$\frac{26 \cdot}{6 \cdot 5 + 4} = \frac{26 \cdot \text{ volts}}{10 \cdot 5 \text{ ohms}} = \text{currrent of } 2{\cdot}47 \text{ ampere.}$$

It will be seen that this arrangement is the one which most nearly gives a resistance of the battery equal to the external resistance, for if we sub-divide again we get 1·625 as resistance of battery, and for current

$$\frac{13}{1{\cdot}625 + 4} = \frac{13 \text{ volts}}{5{\cdot}625 \text{ ohms}} = \text{current } 2{\cdot}31 \text{ amperes.}$$

This arrangement does not, it will be seen, give a current as great as the previous one, which is consequently the grouping that will give the maximum current, and is the one in which the resistance of the battery most nearly equals the external resistance.

NEWS FROM PANAMA.—Intelligence from Panama dated November 16 says:—"The cable steamer 'Duchess of Marlborough' is now in Colon, and is about to proceed to repair the cable thence to Jamaica, which is broken at a point about thirty miles from the point. [This cable has been repaired within the last few days.] The Central and South American Cable Company has determined to cut the T piece out of its line—the shank of which now gives us our connection with the system—and to bring the ends of the northern and southern cables into this city. This will much diminish the power required in transmitting."

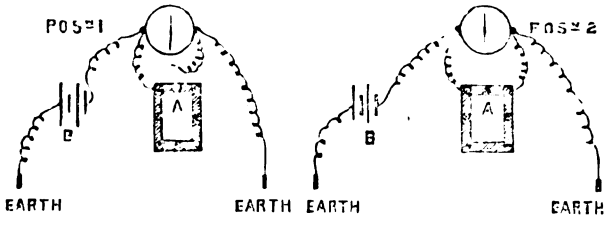
A GUIDE TO PRACTICE IN THE SUBMARINE CABLE TESTING ROOM.

X.

Before commencing to take the constant we must see whether a shunt is necessary, and, if so, arrange it as explained in a former number. The resistance through which we are working is one megohm, and the battery consists of, say, 200 cells. It is possible, however, that the learner may find that there is no megohm at hand; and though this resistance is rarely wanting in a testing room, yet sometimes it is necessary to determine the constant with a resistance no higher than 10,000. We shall presently show how to proceed under such circumstances. For our test we will merely say at this point that with a megohm a shunt will be necessary, and the resistance which it ought to have will probably be on record, as it is chosen with reference to these conditions of standard resistance and battery, also to the resistance of the particular galvanometer employed. But in relation to the cable which is to be tested, a few words are needed to guide the student in the matter of shunt selection.

For a short length of cable, say a few knots, we should, if any were needed, require a shunt of much higher resistance than could be made with coils as generally limited. In fact, the shunt circuit must be broken, technically speaking, and our shunt would have what is called infinite resistance—the shunt would be said to be infinite. A little difficulty may at this point become evident to the learner, arising from the fact that when "infinity" is used for a shunt the test is said to be taken with "no shunt," and he will note that if all the plugs in the shunt-box were inserted there would be no shunt

Fig. 20.



Infinity Shunt (No Shunt.) No Shunt, but Galvr. short circuited.

in circuit, but the results in the two cases would be very different. In the first case practically all the current goes through the galvanometer, in the latter the instrument is short-circuited, and no current passes through it. In Fig. 20, at position 1, we have infinity shunt; in position 2, all plugs are inserted in the shunt-box. In a sense, "infinity" is the highest possible shunt, because it shunts off the least possible amount from the galvanometer. It is best not to use the expression "no shunt" for both cases, but to say "infinity" and "no" shunt respectively.

There is another point not yet mentioned on which the results given by the galvanometer depend, and it applies to all tests. The object being to have a large deflection, yet, of course, within the limits of the scale, all the governing conditions must be taken into account. We have mentioned the battery, the resistance of the galvanometer coils, and the shunt, but one very important feature is the sensitiveness of the instrument. By this we mean the amount of freedom allowed to the little mirror when tending to swing under the influence of the current on the tiny magnet attached to it. Every galvanometer has a controlling magnet, the form almost universally employed being that of a curved bar which slides up and down on a rod mounted in the centre of the cover. Its length is about that of the diameter of the latter. The north pole of this magnet must be on one particular side determined by experiment or a knowledge of the position of the poles of the little mirror magnets. If the controlling magnet is low down on the rod it limits the swing of the mirror considerably, and the higher it is pushed up the rod, the more freely will the mirror deflect. Any alteration, therefore, in its position on the rod must be taken into account in using the instrument, because if the battery and shunt with the circuit resistance were the same at two different times, and the controlling* magnet were shifted, a different deflection would be the result.

To return to the test. Having arranged our shunt, let us depress the left-hand key and clamp it down. The short circuit plug remains inserted for a few seconds after charging, and the operator must be exceedingly careful not to charge unless assured that this plug is in its place. If it were not there the charge would rush through the galvanometer coils, and probably demagnetise the little mirror magnets. Immense trouble has been occasioned by a mishap of this kind. When the little magnets are demagnetised (deprived of their magnetism) they no longer yield properly to the influence of the current through the coils, and deflections given by the mirror are anything or nothing. The controlling magnet also influences the little ones irregularly; the whole thing is upset, and much trouble may occur in repairing the arrangement. The little magnets must be magnetised afresh, and the mirror probably be resuspended, that is, have a fresh fibre attached. We mention this to impress the caution on the learner's attention.

After the 15 seconds above mentioned, the short circuit plug will be removed gently and by degrees, with a slight jarring motion to control the movement of the spot. This will now be seen to move down the scale, and, swinging a little while, more or less according to the care with which the plug has been taken out, will finally come to rest, and its centre marked by a fine line (reflected on to the mirror by means of a wire in front of the light) will mark the division which is the limit of the deflection—we may suppose it marks the 300th. The value for constant is, therefore, 300, and if the multiplying power of the shunt were 150, we should have, as before shown, 45,000 millions for the constant. We have now to take off the battery. But here, again, the caution at first given must be observed. Before releasing the battery key, the short circuit plug must be replaced for the same reason which compelled us to avoid taking it out, except that in this case of taking the battery off it is the *discharge* of the current through the galvanometer that is to be avoided. The million resistance is now to be disconnected, and the cable joined up in its place. The proper shunt must be arranged to cause the deflection to be as nearly as possible the same as that of the constant after the cable shall have been charged one minute. The reason is that the influence of the current in the galvanometer coils shall be as nearly as possible equal in both cases, and therefore a fairer comparison obtained. When a number of cables of the same type are to be tested, it is easy after properly testing the first to arrange the shunt, since a smaller shunt is required as the length increases. The same plan for finding what shunt ought to be used when total uncertainty prevails on the point in this test will not be followed as suggested for a capacity test; for as 200 cells are being used the cable can only be charged once, namely, for the purpose of the test, and beyond this the capacity would not be interfered with as the insulation resistance would, because the conditions are not the same. A little consideration of the explanations already given in relation to these two operations will make the matter clear. For lengths of cable below twenty knots, generally speaking "infinity" shunt will be used, but all depends on the type and quality of the cable and the resistance of the galvanometer employed. When with this shunt we cannot get a readable deflection, it is customary to use 30,000 or 40,000 ohms resistance as the next lower.

Before charging the cable for the test the operator should look over the connections and see that all is right. If the constant has come out satisfactorily there is nothing to change, but all the connections should be tight, and no leads touching each other or anything likely to cause leakage (of the current). Then the key is to be depressed and clamped down. After 15 seconds the short circuit plug is lifted as before and laid aside. The spot will probably pass off at the

* This magnet serves another purpose, but it need not be discussed at this point; it involves considerations beyond the limits of elementary teaching.

Digitized by Google

end of the scale at first, and shortly be seen returning more and more slowly. It must be watched, and, if all is right, will move steadily, always in the same direction, back towards zero. At the end of one minute from the time of charging a reading will be taken, and generally also at two minutes and five minutes; in each case the number of the division marked by the centre line of the spot is recorded. After the fifth minute the short circuit plug will be returned to its place, and then, but not before, the battery key may be released. If other sections of cable are to be tested, they will follow in their turn. When all are finished it will be proper to take the constant again to see if there be any change in the galvanometer coils. It may, perhaps, be found that the deflection is larger or smaller than it was at first. If so, the mean of the two readings should be accepted.

Supposing we were to keep the current on for a considerable time, instead of freeing it as stated, and also keep the plug out, the spot would continue moving back for a period varying with the length of the cable under test. Perhaps after thirty minutes it would be nearly stationary; it is not usual to observe the movement for more than half an hour in any case where the section is perfect, but we mention the time merely to show what passes, and for the purpose of considering the conditions governing the operation.

There are certain points to be noted in connection with this test, and, first, the spot ought to start exactly from zero when the short circuit plug is lifted, and should also return to it when this plug is replaced. When a five-minutes test is taken, it (the plug) should be once or twice inserted to bring the spot back to zero, and if it be found to have shifted, and is not now exactly on the line, the difference must be taken into account. If it is on the other side of zero, say, one division, then one will have to be added to the number of divisions given by the last reading; if it falls one division short of zero, then one less will be counted. At the same time the scale, which is movable, can be pushed either way to bring the line of zero under the centre line of the spot. As all these observations ought to be very accurate it is essential that the galvanometer used should keep its zero well.

Another point to be noticed is that the deflection should be on the same side of zero for both constant and cable test. We are supposing the zero to be in the centre of the scale, though, practically, it might be arranged to make one end the zero point, and to let the spot traverse the whole length; but where this is not done, the deflections can, of course, be made right or left, according to the position of the plugs in the galvanometer commutator. Theoretically the mirror swings equally either way for equal currents and circuits, but in practice it sometimes happens that, under similar conditions, a deflection to the right may be a division or two more or less than on the left. This may be owing to imperfect levelling of the galvanometer stand or to torsion in the fibre by which the mirror is suspended. Therefore it is safer to arrange the four-way commutator as hinted above.

We have said that other forms of commutator are used for regulating the direction of the deflection besides the four-way piece here suggested, and when this is the case, an extra key must be provided for short circuiting the galvanometer. The plug commutator is specially convenient, because it combines the two requirements. In Fig. 21 a double-current key is shown for commutator, and a short-circuit key for admitting or excluding the current from the galvanometer. The short circuit key acts thus—the point G is connected conductively to F by the key piece, which presses against the bar Q, and thus makes a metallic path of (practically) no resistance; if the key be depressed the path is severed, and a current would pass through the galvanometer as the only way open to it. In the figure the battery key is omitted, though in practice it would be employed, as well as the battery commutator formerly illustrated. The comparison of the different arrangements is seen by observing Fig. 22 at the same time with Fig. 21. In the former figure position 1 compares with the effect of depressing the left hand key, L, in the latter, and position 2 compares with that depressing R, the right hand key in that figure. In the first case, by putting down L the current passes to the lower bar, J, and so to G, when, if the short circuit key is depressed, it goes round the galvanometer coils in that direction, entering on the *right* hand (facing us). This is just as it would do in position 1, where it passes to G, and, if the plug is out, goes through the galvanometer on the same side following the arrows. Reversing this direction, and depressing R, the current goes by L to the upper bar, H, L being up and pressing against it, and passes to F, entering the galvanometer on the *left* hand (facing us), that is, if the short circuit key is down. Comparing this with position 2, the current goes to G, and the plug Q, whose

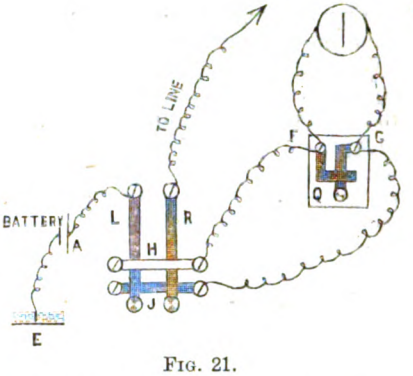


Fig. 21.

place is changed, being removed, passes by F round the galvanometer by the left side (facing us). The only difference is that, in the plug commutator, the current enters at G in both positions (Fig. 22), and, in position 2, afterwards goes by F. In the key commutator, Fig. 21, it enters, in the first case, at G, and, in the second, at F, going *direct;* it comes to the same thing, however. The letter Q in Fig. 21 is repeated in both positions in Fig. 22, as marking in each case the means of opening or closing the circuit—in the former by the small key, in the latter by the plug. The letter G, in

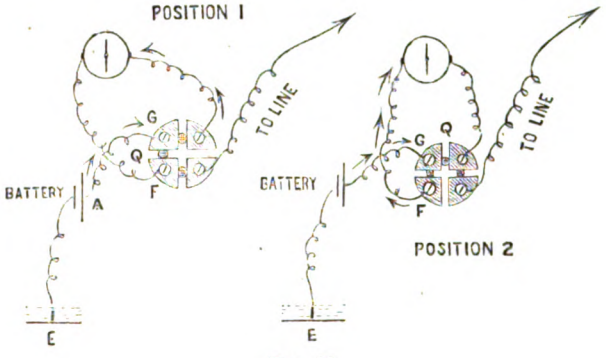

Fig. 22.

positions 1 and 2, is not placed against the galvanometer lead as in Fig. 21; but this is immaterial, as the four-way piece is both commutator and short circuiter. The short circuit is between the terminals of the galvanometer all the same, since the other plug connects G to the next quadrant.

In the next number the subject of the Insulation Resistance Test will be continued, as several points remain to be considered.

The Volta Prize of 1887.—An official notice states that the prize of 50,000 francs, instituted by decree dated the 11th June, 1882 (known as the Volta prize), and intended to be conferred on the author of the discovery which shall render electricity an economical agency either as a source of heat, light, chemical action, mechanical power, means for transmitting despatches or the treatment of illnesses, will be conferred in December, 1887. All nationalities are allowed to compete, and the competition will remain open until the 30th June, 1887. A commission will be appointed by the Minister for Public Instruction, Paris, to report on the discoveries, &c., which may be entered for the prize. Professor Graham Bell was the last recipient of this prize for his researches in telephony.

FIRE ALARUMS.

The season of great fires appears to have set in with unusual severity. Not long ago the alarm created by armed burglars furnished a text for the introduction of alarums to warn the peaceful householder of his danger. The present epidemic of fires seems to call for similar exhortation with respect to peril of a different kind. Bad as he is, the midnight thief is seldom an incendiary, and at his worst does not rob us of as much property as an outbreak of fire generally destroys, nor endanger so much life and limb as it not infrefrequently does. In the case of fire, it is true, there is the insurance policy to fall back upon, whereas against theft there is no such consolation. But from the public point of view, that is to say from the point of view of our common interests, a fire is a calamity, and ought to be regarded in that light by the insured as well as the insurers. Perhaps this fact is a trifle too much overlooked, the Insurance Companies, like the Poor-law guardians, having demoralised us somewhat in respect to personal responsibilities. It needs, or ought to need, no moralist or political economist to teach us that what is destroyed by fire is a dead loss to us all, and is irreparable, notwithstanding the ready response of the fire office. Though scientists may tell us that nothing is really destructible, it affords us no sort of recompense to have our property returned to us in smoke, especially as we have enough of that commodity already. Next to a failure in the natural fruits of the earth, a fire is, in its degree, to be classed as a national disaster. There is no exception to this rule, unless it be the cleansing by fire of fever dens, whose owners refuse to renovate them in any other way, and which may be advantageously lost for the general gain in health.

Elementary as are these notions about the literal destructiveness of fire, they appear to be, as we have already hinted, partially forgotten, otherwise the precautions against such visitations would be far more general and complete than they really are. At this time of year, if we mistake not, the frequency of fires is particularly noticeable. Some people attribute them to the impending Christmas bills, others again to the slack season, whilst others more charitably explain them by the obscurity of the days and the length of the nights, involving the constant, and therefore careless, use of gas light. Be this as it may the fire brigade has little or no rest when the fogs and the frosts set in; and every morning's newspaper brings its quota of fires big and little to swell the winter's total. It is true we hear nothing of the fires that have been instantly put out, or of precautions proving efficacious just when they are wanted; but making allowance for these it does strike one as portentous that so many fires, and fires, too, of such huge dimensions, should do their cruel worst while man stands helplessly by.

For this is really what does happen. In the very establishments where precautions should be of the most painstaking, where the risk is the greatest, and the consequences of neglect the most deplorable, there we never hear of any special safeguards whatever. As to fire alarums, if they exist, they appear to be dumb, and when once a flame is kindled in such edifices all the water that the best engines in the world can shower upon it seems powerless to stay its progress. Electric fire alarums of various kinds have been in the market for a considerable period. If the present quite phenomenal series of conflagrations induces either the owners of property or the insurance societies to promote the adoption of such appliances some good may come of it. We are glad to notice that a company has been formed for the purpose of pushing the sale of alarums of this kind. We know little of the promoters or of the particular device advocated by them; but we heartily wish them success, and that they may profit by what we may call the present excited state of the fire market. The ways of giving timely warning of a fire by means of electricity are so numerous that we need not specify them here. Theoretically, there is no agency which, appropriately used, so readily lends itself to indicating changes of temperature as electricity may be made to do. Many ingenious devices have already proved their efficiency, but there is still plenty of room for inventive skill to find its reward in this particular field of practical usefulness, and now that a company has been started to promote the introduction of such contrivances, a ready sale may be counted upon for any invention that promises real improvement.

To add to the urgency for some additional safeguards or instantaneous warnings nowadays more than ever, it is currently stated that the present fashion of building is peculiarly

Digitized by Google

weak against the assault of fire. We do not allude to the lath-and-stucco "desirable residence" in which the City clerk is compelled to die, or to the mud-built cottage provided by jerry builders for the suburbanised British workman. Saturated with moisture unspeakable, these habitations refuse to burn. But not so the stone-built, iron-girdered "blocks," which of late years it has been the prevailing custom to erect for what are esteemed our City improvements. Bricks which have already stood the brunt of a fierce furnace will, we are assured, stand it once again without injury, and if well put together with honest mortar will survive where stone will crumble to pieces. Add to this the fact that iron, now so universally used in construction, swells inordinately and literally bursts the edifice outwards when subjected to a high temperature, and we have all the conditions requisite for enlarging the area of conflagration and augmenting its material injury. Under these circumstances the necessity for introducing in buildings so constructed a trustworthy and efficient alarum is perfectly evident; and we hope the time is not far distant when this will be one of the conditions upon which future fire policies will alone be granted.

CORRESPONDENCE.

THE ACTION OF MICROPHONES.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In reference to the article by Professor Blyth, from the *Proceedings* of the Royal Society, Edinburgh, contained in your issue of 25th November, which I read with much interest, I cannot accept the result of experiments therein by any means as a proof that resistance of the carbon contact in the transmitter is *not* subject to changes in its normal resistance under pressure, or that the experiment with 20 Grove cells illustrates the action in a transmitter.

Experiments which I have made in this direction lead me to quite a different conclusion—viz., that the microphonic action which takes place in a transmitter *is due* to the variable resistance of carbon, under varying pressures, with a closed contact, and not, as the inference to be drawn from the paper in question would set forth, by a "make and break," or what I will term an intermittent contact.

I trust that the learned professor, and the distinguished physicists referred to in the above paper, will excuse me indulging in a little "rank heresy."

It would seem throughout the wordy warfare which took place in discussing the validity of patents held by the United Telephone Company, that Edison's beautiful instrument, the tasimeter, was completely lost sight of, in which a carbon button varies its resistance under the effect of *pressure* due to the expansion of a solid undergoing a change of temperature. As the tasimeter button in some cases is composed of compressed lampblack, it will be advisable in this case to take an ordinary Blake transmitter, in which a hard carbon button bears on a platinum stud, as a means of demonstrating my experiment.

In regard to the assertion that a loose or intermittent contact exists, I would refer the reader to Diagram No. 1, which shows the working portions of a Blake transmitter in skeleton.

D is the iron diaphragm which is subject to the most microscopic motion only.

P platinum stud suspended by a very thin ribbon of German silver, R, and bearing on the diaphragm D.

C is a button of hard carbon held in a brass cell, B, which is screwed to a comparatively strong steel spring, S, and is forced in the direction of the arrow by an adjustable lever (not shown) against the stud P, and through it the primary circuit is completed, the route of the current being down S, through B and C, to P, thence up R.

The lever in connection with the spring S is adjusted so as to force the carbon button carried by the spring S against the platinum stud P, with a *continuous pressure* in the direction shown 40 to 50 grains. It might be argued that the weight of the carbon block and cell would be sufficient to neutralise this force, but, seeing that the arc described by the carbon button responding to such vibration is excessively small, the *versed sine* or actual lift must be infinitesimal and may therefore be ignored, leaving the continuous thrust of the spring (which is surely sufficient) to overcome the *vis inertiæ* of the mass suspended, and moving in a practically horizontal plane.

Is it, therefore, probable that such vibrations could be imparted by the voice to the iron plate that would be capable of interrupting the continuity of the contact between carbon and platinum, when the iron plate is "damped" by a strong steel spring (not shown), and when the carbon is kept "up to its work" by a force exerted by the spring S, of say 45 *grains?*

The question admits of one answer only, but this I leave for every one to form an opinion thereon from the facts I have given.

This point, however, is not of great importance, for if it can be shown that carbon varies its resistance under minute changes of pressure it proves that microphonic action will take place on a closed contact, and that it is not necessary that an intermittent contact does and should exist, as per the last paragraph of the article herein referred to. It therefore will follow that Professor Blyth is wrong in making the deduction that the microphone is practically a Reis contact.

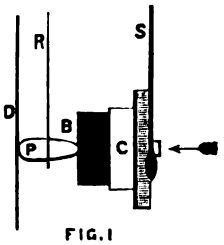

FIG. 1

Regarding "the filling of the gaps with material which is sensitive to the harmonic variations of the atmospheric density," and in illustration of which a diagram of apparatus is given which was used in conjunction *with* 20 *Grove cells* (the italics are mine), all I can make of it is that the professor has constructed a very respectable arc light, and practically demonstrated a question which appeared in a scientific paper lately, "Was the electric arc capable of microphonic actions?" made by some one who had found this action to exist in ordinary flames, but evidently had not the means at his disposal to make the experiments on the arc. Professor Blyth says there was no effect produced when the carbons were in contact, but had to draw them apart, and not until the *electric arc was visible* did the microphonic action take place, which *again ceased* as the carbons were consumed, and the distance from each other had become too great for the current to surmount. It is obvious, therefore, that the action was not produced by the vibration of the carbons relative to each other, but to vibrations of the arc, the carbons being completely divorced and maintained at a *finite distance apart*, a condition which is impossible in a telephonic transmitter.

Further, there is no transmitter in the market which requires 20 Grove cells, and, for the sake of the battery man, I trust there never will be. It is presumable that if the effect could be produced by *one cell* the professor would not have used 20.

The Blake transmitter is one of the best, if not the best and most economic, in the market at the present day, requiring only one No. 2 Leclanché, and from this fact, and the construction of the contact as before described, it is apparent no such effect can exist, and the probability of it ever being made use of for telephonic purposes is very remote.

The method which I adopt to demonstrate the effect of vary-

Digitized by Google

ing resistance is as follows:—I connect up the primary circuit of a Blake transmitter, with the Wheatstone bridge and a tolerably sensitive galvanometer balancing the resistance, as shown in Diagram No. 2.

1st. I find on blowing into the transmitter opening the force exerted by the breath was sufficient to send the pointer of the galvanometer with vigour to the extreme end of the scale, showing that the normal resistance of the carbon has been altered in a very considerable degree; and, 2nd, on separating the carbon-platinum contact, the needle vibrates to the opposite side of the scale, thus proving that the effect in the first case was to *minimise* the resistance. 3rd. Thinking this effect might be caused by an increase of temperature, I used a pair of bellows *with the same result*. 4th. To avoid the vibratory motion which might be set up by the rush of wind, I took a bristle out of an ordinary hearth brush and pressed it against the diaphragm, and found the *greater the pressure put on the bristle* the *greater* the deflection.

Therefore, the resistance varied inversely as the pressure varied, and on releasing the pressure of the bristle *steadily* the needle returned practically without variation to zero, and I have come to the conclusion that the difficulty which is experienced by the needle in regaining the initial position when experimenting with carbon is due to mechanical trituration, and if proper precaution had been taken to eliminate vibration in the above case, when the experiment was performed in a rough and ready manner on a very shaky table, the needle would have regained its original position without appreciable deviation. When I have more time at my disposal I intend going very carefully into this point, and, with your kind permission, will send the result of experiments for publication.

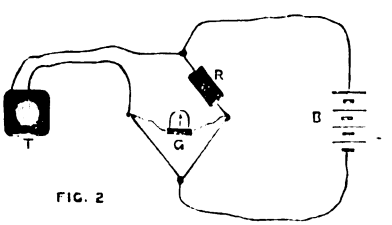

FIG. 2

Could any one conceive the resultant force acting on the carbon exerted by the bristle through the medium of the iron plate? Is it to be wondered at, considering the method herein described, that experimentalists fail to demonstrate the variable resistance of carbon by such means as "vices," "levers," *et hoc genus omne*, even unto the "bending" and "crushing," with which I can only compare an attempt to measure the network of a spider's web with a land chain.

The deductions which I make from the foregoing experiments are, 1st, that the normal resistance of the carbon is diminished on pressure being applied within certain limits, which regains its normal resistance on the pressure being removed.

2nd. The current will be proportionally increased as the resistance is diminished.

3rd. Induced currents will be set up in the secondary coil by the variations of current flowing in primary and in proportion to their intensity.

4th. That the variation of the primary current will be proportional to the vibrations of the diaphragm, which will in turn respond to the magnitude and intensity of the sound waves which impinge on its surface.

Therefore microphonic action takes place independent of an intermittent contact with or without matter filling the gaps.

The rise and fall of the primary current is in a wave like form, and which gradual rise and fall the induced currents will follow. If the intermittent contact theory existed we should have an abrupt or short-stopped effect, and the induced currents would be developed in like manner, giving rise to a harsh crackle, in place of the mellow cadence of a well made and adjusted transmitter. The effect of a slack transmitter producing intermittent contacts is peculiarly characteristic, and once heard not readily forgotten.—Yours, &c.,

R. D. SMILLIE, Electrician.

National Telephone Company (Limited),
Glasgow, Dec. 6, 1882.

CHARGING SECONDARY BATTERIES.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: We have to thank Mr. Bosanquet for pointing out an omission in our paper of the week before last.

Although for convenience of discharging we join the first cells on to the switch five at a time, we find it too great a drop, as he points out, to change from five ohms to five cells, and we now always "flash" the handle round to the second or third stop.

The proper number (x) of cells to replace any given resistance, R, with a current, C, being obtained from the formula $x = \frac{C R}{C\rho + e}$, where ρ and e are respectively the internal resistance and E.M.F. of one cell.

E = E.M.F. at terminals of shunt.
C = current.
R = resistance of shunt.
ρ = internal resistance of one cell.
e = E.M.F. of one cell.

$$E = C R.$$
$$E = C x\rho + x e.$$
$$C x\rho + x e = C R.$$
$$x = \frac{C R}{C\rho + e}.$$

We have generally found that our secondary cells have, immediately after charging, an E.M.F. higher than their normal one; it is, therefore, always advisable, before taking the E.M.F. of an experimental cell, to circuit it for a short period of time through a small resistance.—Yours, &c.,

C. W. S. CRAWLEY,
E. C. RIMINGTON.

"IOLANTHE" AT THE SAVOY THEATRE.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In reading through the description you give of the portable electric lights now employed at the Savoy Theatre, we notice that you do not mention that the specially small incandescence lamps were constructed for the purpose by Mr. Stearn, of the Swan Company, and that his having succeeded in still further modifying their details enables us to reduce the weight of the new batteries to about 3lbs.

At the same time, as we are desirous that credit should be given to whom it is due, we beg to point out that it is our assistant, Mr. Koeppler, who has had charge of the electric light installation at the Savoy Theatre from the beginning, and that Mr. W. S. Rogers, to whom you refer, was only engaged in perfecting the working details of the small portable lights in question.—Yours, &c.,

SIEMENS BROTHERS and Co. (Limited).

PHOSPHOR BRONZE WIRE.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In your issue of the 2nd inst., which has just reached me, I notice a reference to my phosphor-bronze wire, in a table of results furnished by Mr. L. Weiler. I am thus forced, much against my desire, to beg you to insert this protestation. Phosphor-bronze is not, as you state, a new alloy, since the Phosphor-Bronze Company in London was

Digitized by Google

founded upon the purchase of my patent in 1870. Nor is Mr. L. Weiler the inventor of its application for telegraphic purposes, his knowledge on the subject having been acquired from me and his visits to my works whilst he was acting as manager for his brother, who was my agent for the sale of this wire in France.

As long as Mr. Weiler was content to prove the material he sells I have had no wish to rush into print and gain a cheap advertisement; but I am forced to protest against his introducing my manufacture into his tables of comparison for the purpose of showing his superiority, the figures he gives being entirely fanciful and erroneous and opposed to the truth.—Yours, &c.,

G. Montefiore Levi, C.E.

OHM'S LAW.

TO THE EDITOR OF THE ELECTRICIAN.

Sir: I am much obliged by Mr. Harvey's letter, but it does not explain the difficulty which presents itself to my mind. At first sight it appears extremely likely that a conductor having double the capacity would convey double the quantity; but I have not at present tested that fact as I intend to do. I do not see when a river flows much faster in a narrow and shallow part than it does in a broad and deep part—but the same quantity of water passes in the same time—why electricity obeys a different law, and I cannot help thinking that the heating of a finer wire more than a larger one is due to the greater rapidity with which electricity passes. If the effect of resistance is to retard the consumption of the zinc in a battery, or rather I should say the conversion of it, then it appears to me very inaccurate to describe that *portion* of the electromotive force which is used as *the* electromotive force. Nor can I understand when a resistance of 10 ohms would suffer sufficient electricity to pass to raise, say, 100lbs., and a resistance of 20 would only permit sufficient to raise 50, and a resistance of 40 would only permit sufficient to raise 25lbs. (which would be the case if current is to be multiplied by resistance), why 10 ohms, when the increase is from 10 to 20, should cause a reduction of 50, when a further increase of 20 would only cause a reduction of 25. Nor can I understand why the resistance retards the chemical action, which it seems to me it must do unless a force can be created if the quantity passing is to be multiplied by the resistance.—Yours &c., J. A. S.

ELECTRICAL ACCUMULATORS OR SECONDARY BATTERIES.*

BY PROFESSOR OLIVER LODGE.

No. IX.

The coatings of both plates being now fully formed, the one all peroxide, the other all metallic lead, the gas which is liberated against their surfaces is no longer absorbed, but begins to rise in considerable quantities, at the same time that by making the plates into a gas-battery the free gas adds distinctly to the electromotive force of the cell. The fulness of the cell can therefore be told in these two ways—a greater escape of gas and a higher opposition electromotive force than usual.

The proper or "ohmic" resistance of the cell is now a minimum, however, for three reasons—because the conducting surfaces, the front surface of the peroxide and the front of the reduced lead, are as near as they can possibly be; because the acid in the solution is as concentrated as it can become, that which had been absorbed by the lead having been restored; and because the cell will have been warmed by the charging current. The cell is, therefore, in all respects at its very best, and it can give a tremendously powerful current for a few seconds if called upon.

But suppose it is not called upon for a current, but simply allowed to stand idle for a time, what will happen to it? First, of course, it will cool, and thereby slightly increase its resistance; but, more important than this, the gas which is clinging mechanically to the surface of the plates will collect in bubbles and gradually rise, thus lowering the electromotive force from its abnormal value. The gas which first escapes, however, will be the oxygen; a large quantity of hydrogen will remain half alloyed with the lead plate, more especially, perhaps, if it is amalgamated, and accordingly the electromotive force, though it loses its abnormal value, retains a perfectly satisfactory one.

No further change of importance need be expected to be noticed after the lapse of several minutes or even an hour, but if the cell is set aside for a day or two a more serious change sets in. The front surface of the lead loses some of its hydrogen, and is liable to be corroded slowly by the acid, a slight scum of insulating sulphate being produced; and these changes, though they go on with extreme slowness in a good cell with its terminals properly insulated, yet are exceedingly weakening when they do occur, because they lower the electromotive force and increase the internal resistance at the same time. A plate well saturated with hydrogen, however, will resist the formation of any such scum for a considerable time, and I see no reason why it should form in any quantity for a week or so, provided there is no leakage between its terminals. I apprehend, however, that a temporary short-circuiting of the full cell before setting aside, whether for the purpose of testing or for other purposes, would have a detrimental effect by diminishing the store of hydrogen, and that a cell so treated would not bear standing idle quite so well as a perfectly full one.

The main part of the change which occurs during standing seems to take place at the + plate. Here the peroxide is in contact with and supported by a plate of metallic lead, and the peroxide is sufficiently porous to allow some of the acid liquid to penetrate to the junction of the two substances; hence there is here a complete battery, and, accordingly, a certain amount of local action sets in, some of the lead becoming oxidised and sulphated, while some of the peroxide gets partially reduced. If this action goes on to any general extent it is most disastrous, for the effect is to establish a non-conducting film or layer of sulphate and lower oxides between the lead plate and the rest of its peroxide coating; and it may sometimes happen that the coating is thus completely detached from the plate so as to become quite useless. But, suppose it only gets detached in patches, the internal resistance will thus be increased, and the storage capacity will be diminished almost by the total amount so detached, but the electromotive force would not be likely to be diminished until the effect of the local action had extended itself through the whole *thickness* of the peroxide. After a long time it, probably, would so extend itself, and thus the peroxide would get reduced by mere standing without any current having been demanded from the cell.

Messrs. Gladstone and Tribe have called attention to this local action, and pointed out one reason why it goes on more slowly than might at first sight have been expected, viz., that the crust of sulphate formed on the lead protects it by its insulating power, and only permits deeper portions to be acted on by reason of its porosity. Another reason why the action is not at all rapid is that the surrounding mass only permits a very insignificant amount of circulation in the liquid, so that it soon gets exhausted of its acid, and is only slowly replenished by diffusion. Still the local action does go on more or less rapidly, and it is, so far as I know, the main cause of the loss of power of the cell while standing. Moreover the differences noticed among different cells seem to depend very greatly on the facilities which some seem to offer to this action, and to the consequent greater or less detachment of the peroxide coating. Why the coatings detach themselves in some cases more readily than in others is by no means clear; but it may happen that a too rapid evolution of gas, caused by a too powerful charging current, might mechanically effect a separation between the plate and its coatings. It must be remembered, however, that the coatings may easily become electrically detached by an insulating

* Reprinted from *The Engineer*.

Digitized by Google

film—especially in patches—and yet their mechanical adherence may remain almost unimpaired.

The naturally occurring cure for these evils would be either to support the peroxide on carbon, or other such non-attackable substance, or else to use no support at all, but to make the plate wholly of peroxide. But though the use of carbon would do away with local action, scarcely any form of carbon can resist the action of nascent oxygen, and accordingly its surface crumbles during charging, and the powder makes a worse barrier than ever to good conductive connection between the plate and its coatings; in fact, the coatings are liable in time simply to drop off. The use of peroxide alone looks hopeful, but when the cell is discharged and the peroxide reduced the plate will no longer be a conductor, and it does not appear probable that such a cell could ever be charged up again. Moreover, the difficulties of making good and permanent contact with such non-metallic substances are considerable, and their use would, therefore, be very inconvenient.

REPORT ON ELECTRIC LIGHTING.

Vestry of Chelsea.

This report, to which we referred in our last issue, and which is signed by the surveyor of the vestry, Mr. Geo. H. Stayton, Assoc. M. Inst. C.E., and dated Nov. 14, has been published in pamphlet form, and is of considerable interest. A considerable portion of the report is occupied in discussing the various clauses of the Electric Lighting Act, the main objection to which, in respect to present action, is summed up at page 14 as follows:—"It certainly appears most unfortunate that in order to obtain priority of application local authorities are compelled to decide so hastily, and have not been allowed reasonable time to fully consider the subject, and to obtain definite information as to the probable commercial success of such an undertaking." The local authorities, the report goes on to say, "must, therefore, look to the Board of Trade in a great measure for protection against the inconveniences which may arise in consequence of their hands being forced, as it were, by the action of certain speculative companies, who have indiscriminately given notice of application for licenses and provisional orders, not only in the metropolis, but throughout the country."

With a view to obtaining information on various preliminary points necessary to be cleared up before the vestry could be advised to act one way or the other, Mr. Stayton drew up a series of questions to be answered by the several companies who had given notice of their intention to apply for licenses or provisional orders for the lighting of the Chelsea district by electricity. The applicants for licenses by the Board of Trade were from the Metropolitan Brush Electric Light and Power Company and the Jablochkoff Electric Light and Power Company; whilst notices of intention to apply to the Board of Trade for provisional orders had been served on behalf of the Metropolitan Brush Electric Light and Power Company, the Edison Electric Light Company, the Swan United Electric Light Company, the "Pilsen" "Joel" and General Electric Light Company, the Gulcher Electric Light and Power Generator Company, the West Middlesex Electric Light Company, and Messrs. Ferranti, Thompson, and Ince (Limited). To these applicants, and also to Messrs. Siemens Brothers, who, although not applicants themselves, had had considerable experience in electric lighting, Mr. Stayton addressed the following letter:—

Electric Lighting.

Vestry Hall, King's-road, S.W., Oct. 12, 1882.

Dear Sirs: I am instructed to further report upon this question with special reference to the various notices which have been given to the vestry under Sections 3 and 4 of the Electric Lighting Act. I send you herewith a map of this parish, and I may mention that it contains about 40 miles of streets and 12,000 houses. The existing street lighting is effected by 1,250 gas lamps, at an annual cost of £4,500, the price of gas being 3s. per thousand cubic feet. I shall be obliged if you will be so good as to answer the following questions as far as possible at your earliest convenience.

From eight of the companies so applied to Mr. Stayton obtained answers. The Gulcher Company and the "Pilsen" "Joel" declined to proceed with their applications, whilst from the West Middlesex Company no acknowledgment was received.

Commenting on these answers the surveyor to the vestry observes that "whether from indifference or inability" on the part of the companies he is unable to say, "but the result of the inquiries is undoubtedly disappointing, as many of the answers are very indefinite or incomplete. None of the companies have definitely touched upon the question of first cost, but I am of opinion that the probable cost of a complete and efficient installation for the entire area of Chelsea (exclusive of the outlying district of Kensal New Town) would be £375,000. To further consider such a question is totally unnecessary; but to bring the question within a more practical sphere, I have prepared an approximate estimate of an installation in the most suitable parts of Chelsea, based upon the particulars supplied by the evidence of Dr. Siemens, Dr. Hopkinson, Mr. Johnson, Mr. Crompton, and from other and more recent information, which may be summarised as follows, viz.:—

"Estimate for completing an installation of 21,000 'incandescent' lamps for the 1,400 houses, shops, and public buildings, and 120 'arc' lamps for six miles of street lighting, in King's-road, Sloane-square, Sloane-street, Cadogan-place, Cadogan-square, Pont-street, Lowndes-square, Hans-place, Oakley-street, Chelsea Embankment, Beaufort-street, Elm Park-road, Elm Park-gardens, and Fulham-road.

Land, buildings, offices, &c., for two electric stations	£15,000
Engines and dynamos (2,200 h.-p.)	28,000
Fixing and installing	3,000
Conductors (8¼) miles)	25,000
Service and meters (1,400)	5,500
Preliminary expenses and contingencies	8,500
Total	£85,000

"(c) The only definite proposition as to price for the supply of electricity that I am aware of is that of the Metropolitan Brush Company, who consider that 'about 6d. per 1,000 erg-hours of electricity' is desirable. This price worked out and compared with gas at 3s. per thousand cubic feet, is about double.

"N.B.—An erg-hour represents an amount of energy exerted equal to $\frac{1}{746}$th part of a horse-power.

"The probable annual working cost of the minor installation I have described would be from £18,000 to £20,000, irrespective of interest and repayment of capital, and renewals. The estimated annual amount now paid for consumption of gas in the area mentioned (allowing £10 per house) is £14,300; and if the foregoing figures are at all reliable, it is manifest that a profit could not be made except at a charge greatly in excess of gas, *even if all the houses took a supply of electricity*, which, of course, is extremely doubtful."

Mr. Stayton concludes his report by an expression of opinion that although gas has done good service in the past, and will continue in use both as an illuminant and heating power, it will be gradually superseded by the electric light. For the present, however, he does not advise the vestry over which he is surveyor to embark in any venturous changes on its own responsibility, especially as there are companies prepared to undertake the experiments without risk to the ratepayers. He recommended the vestry not to apply either for a license or a provisional order, but to support the application of any company who may appear most likely to carry out such undertaking in a satisfactory manner, and who will agree to any conditions suggested by the vestry and approved by the Board of Trade. These recommendations, as stated in our last issue, were unanimously approved and adopted by the Chelsea vestry last Tuesday week.

Western and Brazilian Telegraph Company.—The traffic receipts of this company for the week ending December 8 were £2,526, after deducting the "fifth" of the gross receipts payable to the London Platino Brazilian Telegraph Company (Limited).

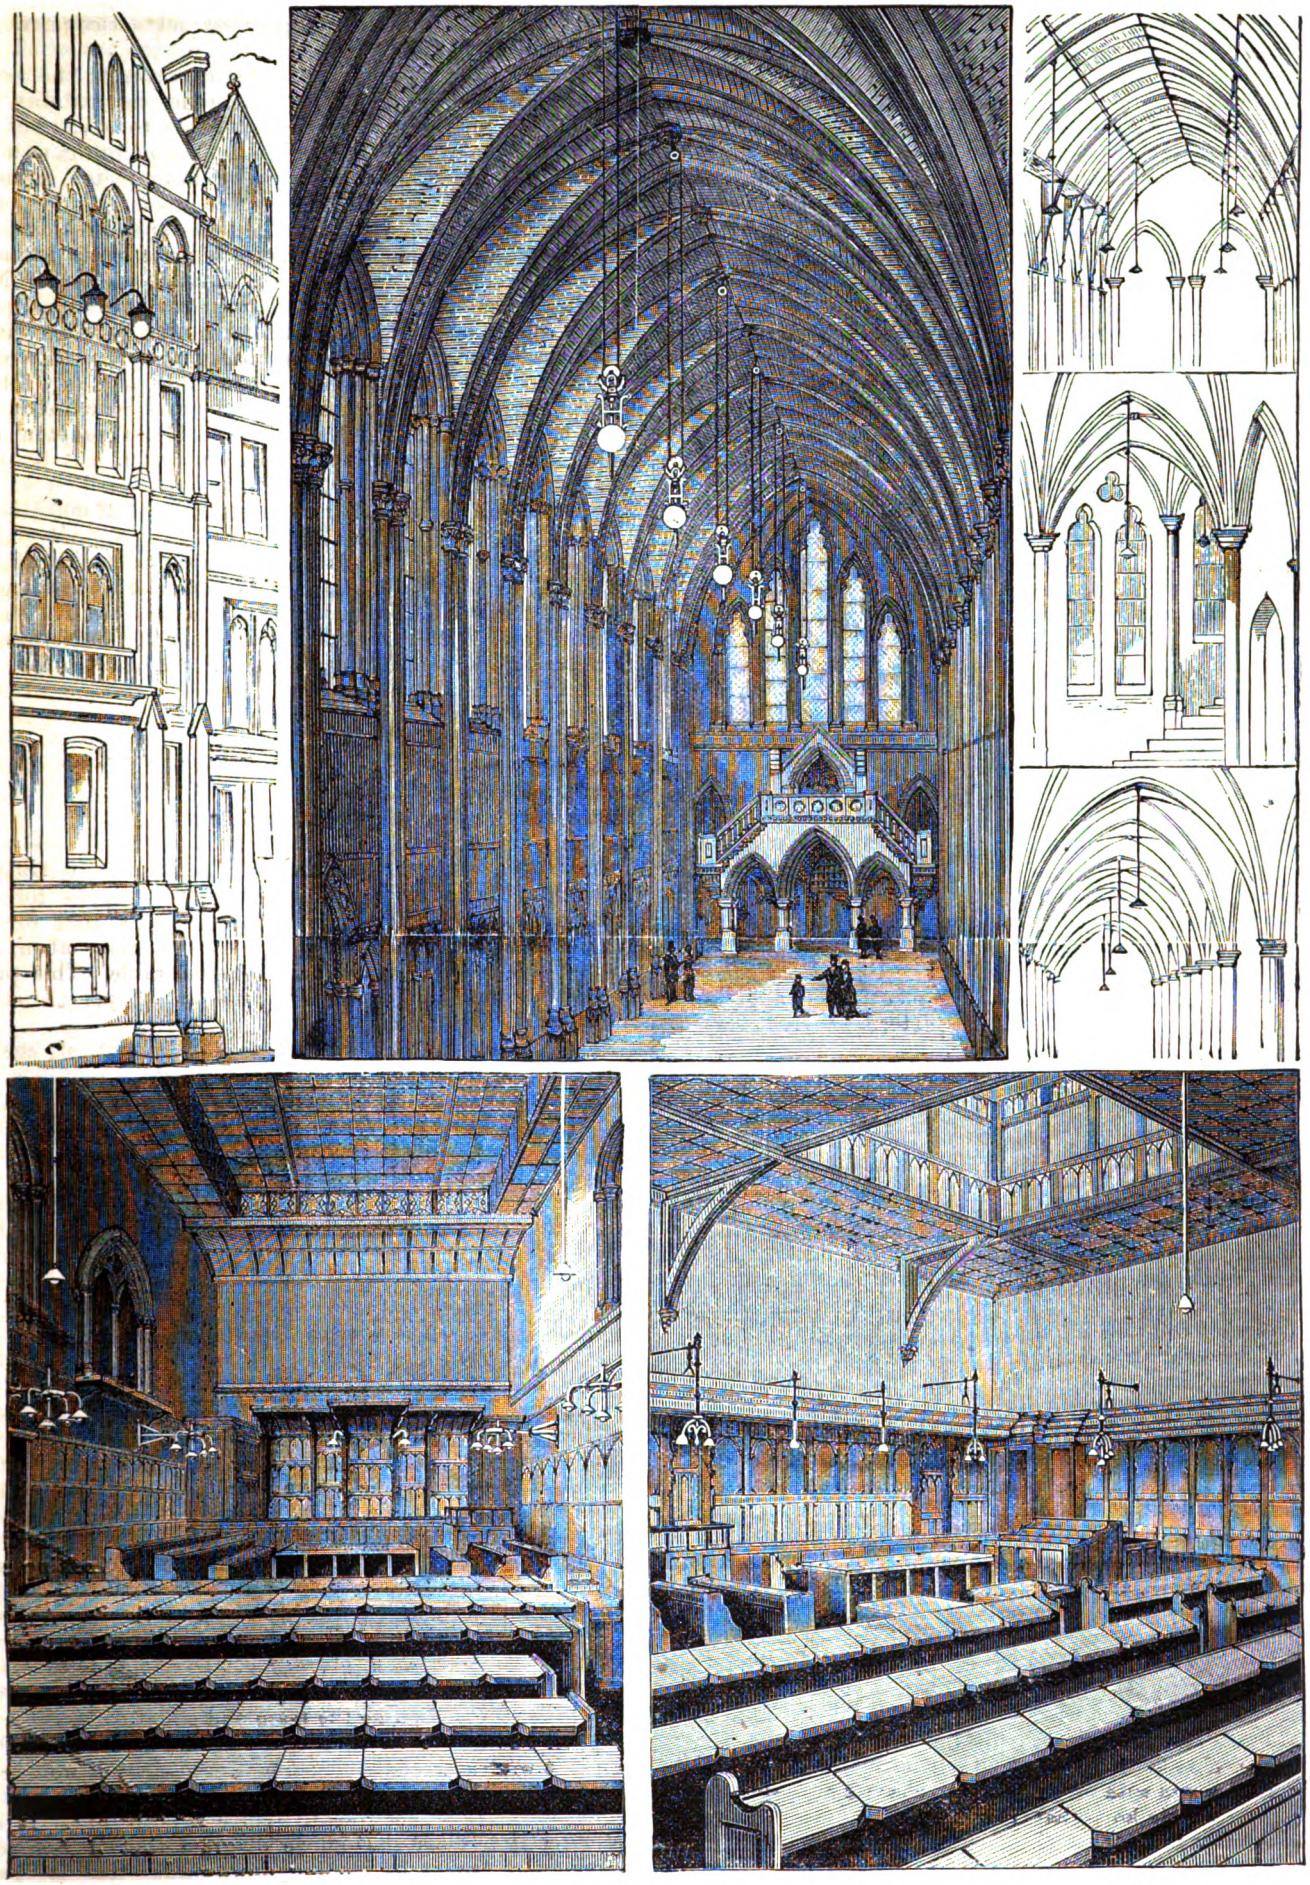
THE ELECTRIC LIGHT AT THE NEW LAW COURTS.



We this week illustrate the interior, as seen on the day of the formal opening by the Queen, of the new Law Courts. Our illustrations show the large hall lighted by six arc lamps, but these are to be replaced by clusters of incandescent lamps.

Digitized by Google

Below this two courts are represented lighted by Swan lamps, the side sketches showing, on the left, the arc lamps lighting the Quadrangle; on the right, the bar corridor, the staircase, and the crypt. As we have previously said, the arc lamps were used temporarily, and will be replaced by clusters of incandescent lamps. The illustrations given to-day will show the general arrangement of the lamps, the style of fitting adopted, while future illustrations will give other details.

CROMPTON'S COMPOUND MACHINE.

BY GISBERT KAPP.

Early last spring the writer was engaged in carrying out a series of experiments with shunt-wound Bürgin dynamos, and in discussing the results obtained with Mr. Crompton, the question was considered whether, by the combined use of shunt and main coils, it would not be possible to make a machine, the external current from which would, within reasonable limits, be an exactly pre-determined function of the external resistance. The choice of this function would, of course, depend upon the purpose for which the machine was intended.

If, for instance, it were required that the current should vary inversely as the resistance, a certain definite proportion of shunt and main coils would have to be used, and the machine would be suitable for working at constant speed a varying number of incandescence lamps in multiple arc.

If, again, it were desired to make the current within certain limits independent of the resistance, another proportion of shunt and main coils would have to be used, and the machine would be suitable for feeding a varying number of arc lights in series.

These are the two extreme cases of greatest practical value for electric lighting, but it is quite possible to design machines which will, within reasonable limits, satisfy any other function between current and resistance, and thus be suited to a variety of other than lighting purposes.

After carefully considering this question, Mr. Crompton decided to test the soundness of the principle by applying it to one special case, viz., that of the external current varying inversely as the external resistance.

For this purpose a series of exhaustive experiments were carried out which ultimately resulted in the production of the Crompton-Bürgin compound dynamo, a machine intended to maintain a constant electromotive force in the outer circuit.

My attention was lately called to an article by M. Hospitalier, which appeared in No. 20 of the French paper, *L'Electricien*, and in which the idea of obtaining a constant E.M.F. by the combined use of shunt and main coils was foreshadowed; and quite recently other writers on electrical matters have touched upon the subject, but with the exception of Messrs. Crompton and Co., no makers of dynamo machines in England seem to have brought the matter to a practical issue, the reason for this, perhaps, being that, in electricity, like in other engineering problems, general ideas alone are not sufficient to make a successful invention. They must be supplemented by a good share of practical detail, only obtainable through exhaustive and careful experiments.

The want of some sort of automatic apparatus which would regulate the current to the number of lamps in circuit has long been felt, and several electro-mechanical devices have been invented and added to ordinary machines with a view of making them suitable for this class of work. But if it be remembered that any kind of exterior regulator can only begin to act after the disturbance, which it is intended to avoid, has already commenced to take place, and that even the most delicate mechanical contrivance must necessarily be clumsy and sluggish in comparison with the lightening speed with which electrical charges are propagated, there seems little hope that regulation can ever be obtained by such means. Yet the electro-mechanical regulator should not altogether be discarded; its proper place should be to assist the centrifugal governor of the engine in keeping the right speed. It will be shown further on that even the regulation of Crompton's compound machine, although perfectly sufficient to protect the lamps from injury, and giving them a current which is constant enough for most cases, is not mathematically perfect over the whole range for which the machine is designed, and therefore it is desirable to have an apparatus which will vary the speed of the engines, so as to make the regulation mathematically perfect. It will be shown further on that this variation need in most cases not exceed from 4 to 6 per cent. up or down from the mean speed.

As far as our present knowledge permits us to judge, the solution of the problem how to work incandescence installations seems to be the following: Employ machines which are as much as possible self-regulating, and make up for any slight deficiency in their regulating power by an electro-mechanical governor, which should assist the usual engine governor or take its place.

Before entering into a theory of compound machines and the rules for their design, it will be useful to consider in a general way their principle and mode of action.

In any self-exciting dynamo working in a closed circuit we have to distinguish between four different electromotive forces.

First, that inside the armature $E\,a$; secondly, that at the brushes $E\,b$; thirdly, that at the terminals of the machine $E\,t$; and finally, that between the two main leads $E\,l$ at the point where the external work is done. If the leads are very short, and of ample section, then $E\,l = E\,t$, but generally speaking we have

$$E\,a > E\,b > E\,t > E\,l.$$

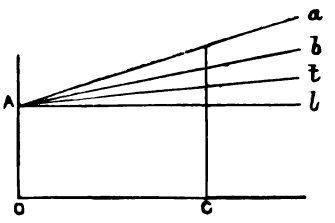
In a given dynamo and circuit the difference between either two of these quantities will vary directly as the current. Now, a perfectly self-regulating machine ought to keep $E\,l$ constant, and this necessitates that $E\,a$, that is, the total electromotive force of the machine, should be a function of the current of the form

$$E\,a = E\,l + e\,C,$$

where C is the current, and e a co-efficient depending upon machine and leads.

This can be shown graphically.

Plotting currents on the horizontal, and the corresponding electromotive forces on vertical lines, we get a diagram like the annexed:—



$O\,A = E\,l$ is the desired constant electromotive force at the chosen point between main leads.

$A\,l$ must, therefore, be a horizontal line.

The electromotive force at machine terminals is now determined by the inclined line $A\,t$, and the tangent of inclination equals resistance of main leads. Similarly the electromotive force at the brushes is given by the inclined line $A\,b$, and the tangent of the angle $b\,A\,l$ equals resistance of exciting coils + resistance of leads.

The total electromotive force is given by the line $A\,a$, and the tangent of angle $a\,A\,l$ equals total resistance of machine + leads.

In the last issue of this paper Mr. Bosanquet gives a formula for proportioning the main and shunt coils.

I shall show later on that this formula is incorrect, but even if it were correct the machine designed by it would not be a self-regulating one, inasmuch as the condition aimed at is to keep the total electromotive force $E\,a$ constant. It will easily be seen from the above diagram that if $A\,a$ be a horizontal, $A\,l$ must be sloping downwards—that is to say the external electromotive force between main leads decreases with an increasing current. The problem is not to keep the

Digitized by Google

electromotive force in the armature constant, but that which is available for outside work, and, inasmuch, as it is impossible to make a machine which has absolutely no resistance, the problem can only be solved by arranging matters so that the electromotive force in the armature rises as the current increases. But the solution will be the easier the lower the resistance of machine and leads.

It was shown above that for perfect regulation A a should be a straight line, but experience and theory teach that this line is always gently curved, and this is the reason why the compound machine is not a mathematically perfect regulator over the whole range of current for which it can be used. If the regulation be required within such limits that the curve can be considered coincident with its tangent, then it will be perfect; beyond these limits, the slight variation in speed mentioned above will be necessary to make it mathematically perfect.

(TO BE CONTINUED.)

ON THE HEATING OF COILS THROUGH WHICH ELECTRIC CURRENTS ARE FLOWING.

BY PROFESSOR G. FORBES.

I have already published the law connecting the strength of current which is permissible in wire coils of equal size and weight when these are wound with wires of different thicknesses. We now require the law when the size of the coils is varied. The problem is as follows:—*Two bobbins of similar proportions have their linear dimensions in the ratio of* n : 1, *and the thickness of wire on the two bobbins is also in the ratio of* n : 1. *What ratio of currents is required so as to raise both to the same temperature?*

Let C, R, H be the current in the smallest coil, the resistance of that coil, and the heat generated in that coil.

Let C′, R′, H′ represent the same for the coil of n-fold dimensions.

Then we have

$$C^2 R = H \quad . \quad . \quad . \quad . \quad . \quad . \quad (1)$$

$$C'^2 R' = H' \quad . \quad . \quad . \quad . \quad . \quad . \quad (2)$$

$$R' = \frac{R}{n} \quad . \quad . \quad . \quad . \quad . \quad . \quad (3)$$

Also, since the temperatures are equal, the heat radiated and conducted in the two cases is in the proportion of their surfaces, *i.e.*, of n^2 : 1. And the heat radiated and conducted is equal to the heat generated. Hence from (1) and (2)

$$H' = n^2 H$$

and $$C'^2 R' = n^2 C^2 R$$

or (by (3)) $$C'^2 \frac{R}{n} = n^2 C^2 R$$

$$\therefore C'^2 = n^3 C^2$$

and $$C' = n^{\frac{3}{2}} C$$

To test the accuracy of this law Mr. Robert Goodwin has made the following experiments for me:—Coils of wire were wound upon two bobbins, whose dimensions are

Small Coil.—Length = 50mm., diameter of tube = 13mm., diameter of wire = 1·05mm.

Large Coil.—Length = 100mm., diameter of tube = 25·7mm., diameter of wire = 2·09mm.

The temperature was in each case raised to 63° Cent. According to the above theory the currents should be in the proportion of $2^{\frac{3}{2}}$: 1 or 2·83 : 1.

At the temperature of 63° Cent. the tangent galvanometer showed a deflection of 37° with the small coil, and at the same temperature with the large coil the deflection was 64°. The tangents of these angles are 0·75355, and 2·0503 respectively, the ratio of which is 2·72 : 1, which agrees very closely with the theoretical value.

THE CHERTEMPS-DANDEU DYNAMO MACHINE.

A number of machines are now being introduced to the public, and it is hoped by each inventor that his machine will prove generally better than those of his competitors. We, together with other gentlemen interested in electrical progress, have been invited to see the dynamo known as the Chertemps-Dandeu at work. It is impossible to do more than obtain general impressions by seeing a machine at work. In order to obtain a comparative value for a machine it is necessary to carry out a series of experiments, and to very carefully collate the result with those obtained from other machines. Before describing the construction of this machine we may give the reports of Mr. Robert Sabine's investigations. These reports are addressed to R. Applegarth, Esq., whose name is well known to those interested in electric light work, and who has introduced this machine into England:—

"I have examined the dynamo electric machine of Messrs. Chertemps and Dandeu with the following results. I found the machine, which is designed to sustain ten Jablochkoff lamps, to be very compact and well made. It is on the alternative current principle, and self-magnetising. Its conducting coils are made to rotate, while those of the induced circuit are stationary, an arrangement which greatly facilitates any necessary supervision or manipulation of the main circuit while the machine is in motion. The supporting frame of the induced bobbins is constructed entirely of insulating material for the purpose of avoiding the development of the so-called Foucault currents; and this is unquestionably a means of saving engine-power, and working the machine more economically than would otherwise be the case.

"Phonometric measurements were made with two up to eight Jablochkoff lamps in circuit, when the machine was driven by a four (nominal) horse-power steam engine, of which indicator diagrams were simultaneously taken, and it was found that the power expended in the machine short leads and lamps increased as follows:—

Lamps on Circuit.	Engine-power Expended on Machine Leads and Lamps.	Speed of Machine.
2	1·28 h.-p.	1150 rev. per minute.
4	2·27 h.-p.	
6	3·60 h.-p.	
8	4·25 h.-p.	

"The average illuminating power of the lamps was 323 standard candles (actual) during these measurements.

"Similar measurements with 10 Jablochkoff lamps and upwards in the circuit were made with the aid of a 20 (nominal) horse-power steam engine, which enabled a greater velocity of rotation to be steadily maintained.

"When 10 lamps were in circuit, the machine being driven at 1,226 revolutions per minute, the engine-power expended in machine, leads, and lamps, was 5·65 horse-power, the average illuminating power per lamp being 430 standard candles (actual), or an effective equivalent of 762 standard candles (actual) per horse-power expended, which is as high as can be expected for a small machine.

"The light given by the lamps was remarkably steady, and the carbon rods were consumed very uniformly.

"At the desire of the inventors, as many as 16 Jablochkoff lamps were at one time introduced into the circuit, and burnt steadily. While 14 lamps were burning, the average illuminating power was found to be 388 standard candles per lamp. The machine after being at work for two hours did not show any signs of heating so long as the number of lamps did not exceed 10, but when 16 lamps were sustained the stationary induced magnets became after a while heated, the rest of the machine and the moving bobbins remaining cold. I conclude from this that not more than 12 Jablochkoff lamps, each giving a light of about 400 standard candles (actual), could be safely worked continuously by this little machine.

"The commutator which directs the currents from one of the stationary electro-magnets into the magnetising circuit works against the brushes perfectly free from sparks.

"In the foregoing tests the coils of the machine and the lamps in circuit were connected up in series.

"The terminals of the machine are, however, arranged so that the current of each induced bobbin may, if required, be connected so as to actuate a separate and independent lamp circuit.

"A very ingenious arrangement is employed for short-circuiting each of the induced bobbins by the armature of a small electro-magnet, which falls upon the terminal blocks in the event of a rupture of the outer lamp circuit.

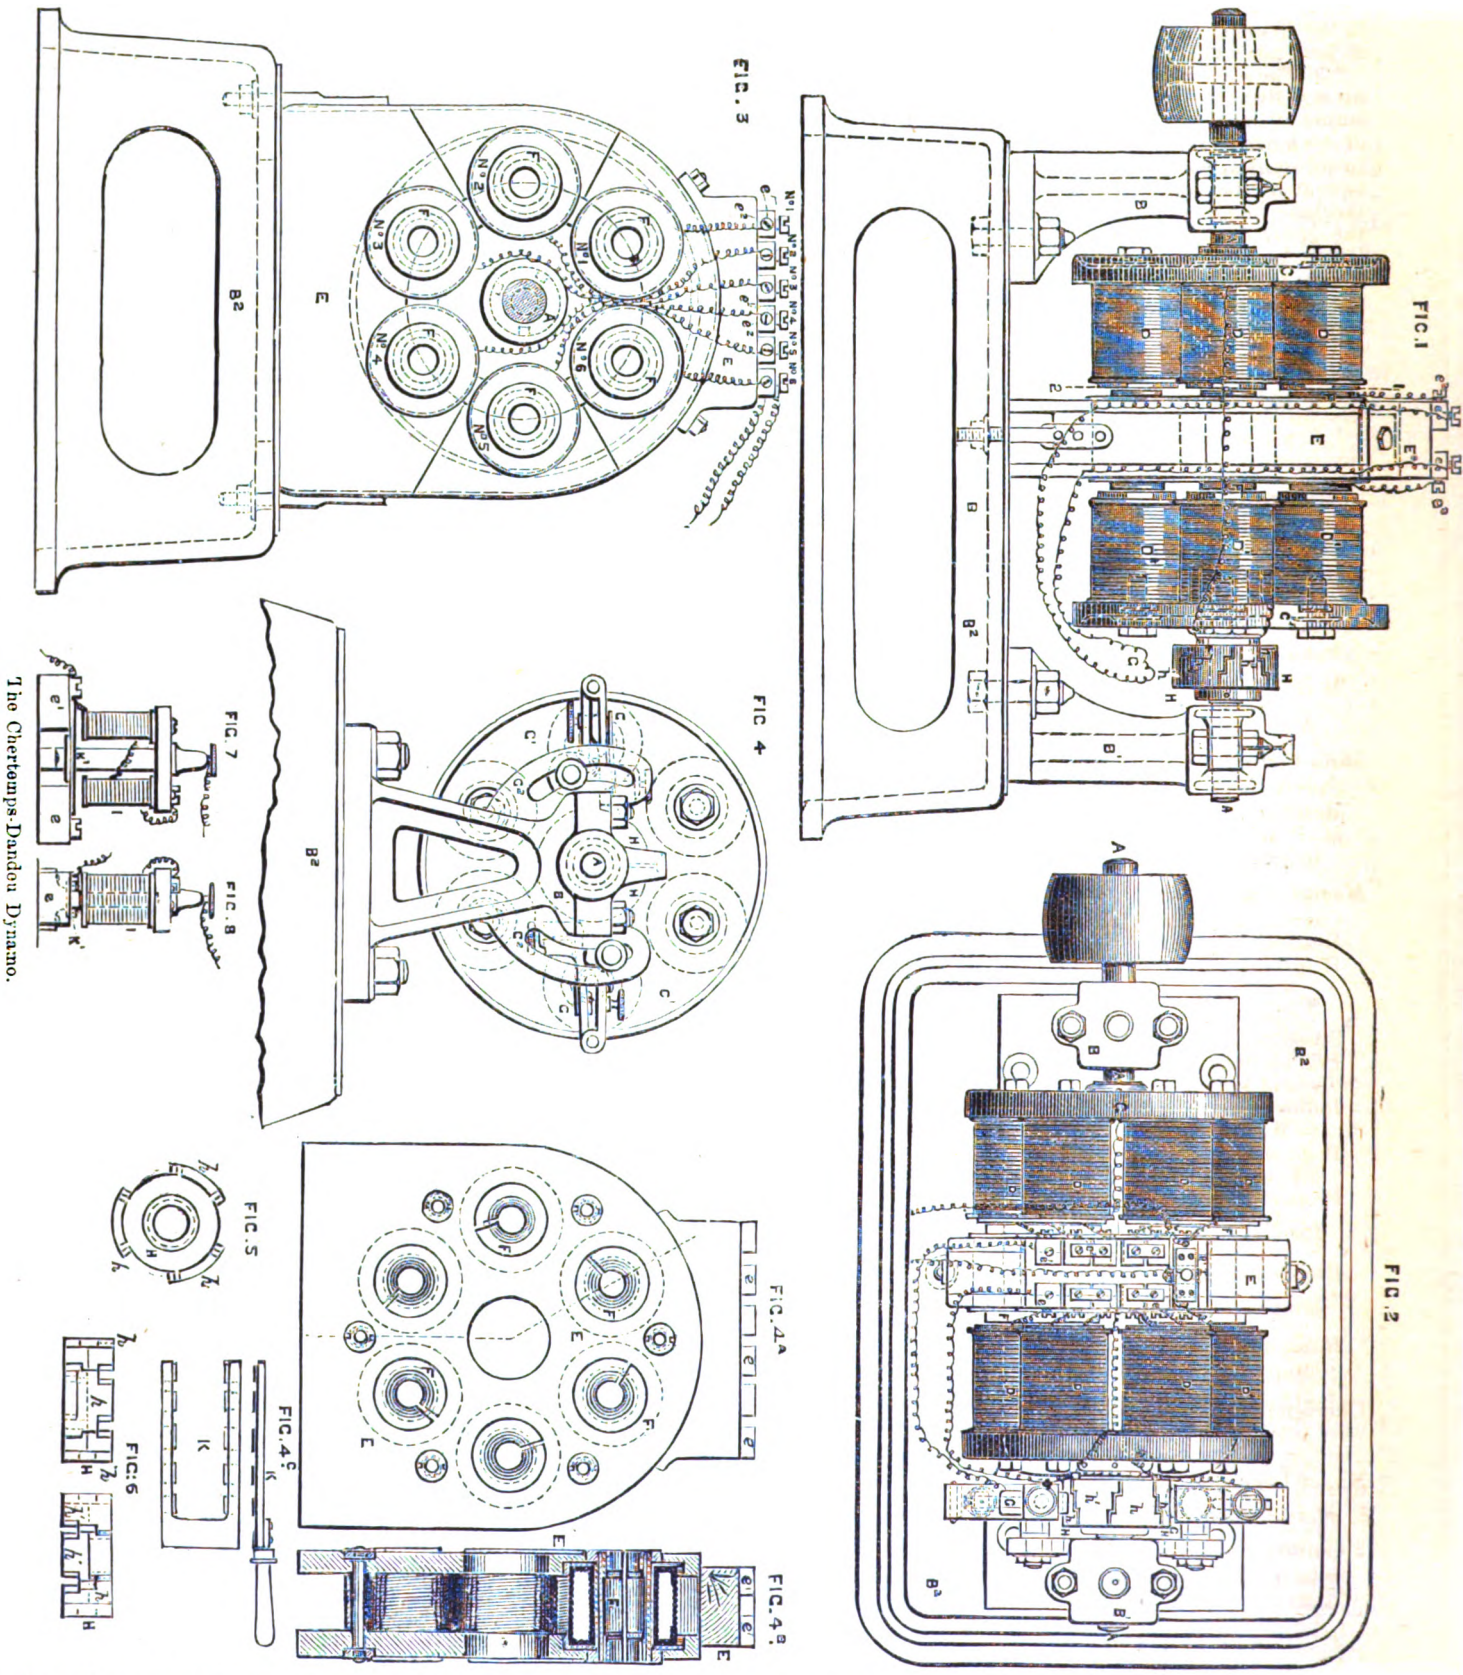
"In point of cost, I should say that this machine would cer-

Digitized by Google

tainly be the cheapest I have seen capable of keeping an equal number of lamps in action, and I quite endorse the inventor's statement that it might be produced and sold at a price which would leave a very good margin of profit.—Yours, &c.,

(Signed) "ROBERT SABINE."

The Chertemps-Dandon Dynamo.



Second report on the Chertemps dynamo machines :—

"I have at your request tested two of the Chertemps machines which you have at Charles-street, Hatton-garden.

"In reply to the questions asked in your letter to me of the 24th November, I beg to say that—

"1. I find that the smallest machine (alternating current) keeps 20 Edison A 16 candle lamps incandescent at an expenditure of about 2 horse-power, as indicated by M. Morin's dynamometer, which is placed between the steam engine and the machine.

"The maximum number of lamps which I saw in circuit at one time was 25, which number was then reduced by five at a time. The horse-power indicated by the dynamometer fell each time proportionally to the number of lamps removed from the circuit.

"2. The medium-sized machine, when giving alternate currents with its induced bobbins parallel, was put in circuit with 52 Edison A lamps, which were kept incandescent at an average

Digitized by Google

of 17·5 candles, with an expenditure of 6·2 horse-power indicated by the dynamometer. The machine was afterwards connected up so as to give continuous current, the same number of lamps being kept incandescent at an average of 15·1 candles per lamp, while the indicated horse-power was 5·1, showing that in so far as lighting power goes circuits with alternate and continuous currents generated by the same machine give much the same result. In each instance over 80 per cent. of the power given to the dynamo machine was accounted for electrically, and over 65 per cent. was accounted for in the lamps alone.

"3. The same machine, with its induced bobbins in series, and giving alternate currents, was then connected with and kept in action 10 Jablochkoff lamps, also in series, at a total expenditure of 4·9 horse-power indicated by the dynamometer as being given to the dynamo machine. The number of lamps was changed by two at a time, and the difference of the power given to the machine being observed at the dynamometer, it was seen that the power employed was always proportional to the number of lamps in circuit, the machine regulating this automatically. When maintaining the Jablochkoff lamps about 80 per cent. of the power given to the dynamo was accounted for electrically, and with over four lamps in circuit about 65 per cent. was accounted for in the lamps alone.

"I consider that, having regard to their size and weight, the efficiency of these dynamo machines, both for arc and incandescent lamps, is very satisfactory.

"I enclose the details of the tests made with the larger of the two machines.—Yours, &c., "ROBERT SABINE."

* Current in amperes, E.M.F. in volts, resistance in ohms.

* The carbons in these measurements were apparently of inferior quality.

The accompanying figures will almost explain themselves. Figs. 1 and 2 are respectively an elevation and a plan of the dynamo. The shaft A is mounted in plummer blocks, B B, secured to the base B_2. The shaft carries a pair of cast-iron discs, C C^1, to which, and inside the field, hollow electro-magnets D are fixed. Between the field magnets is the armature, which is stationary, composed of non-conducting material, E and pierced with a ring of holes. The axis of the ring of holes corresponds with the axis of the field magnets, and the diameter is such as to arrange for the armature magnets to be opposite the field magnets as these latter rotate. The armature coils fit into these holes, and consist of a hollow core of iron tubes wound with wire, as shown in section in Fig. 4*b*. The armature carries six of these coils (Fig. 3) and the connections made, as shown, to terminals carried by an insulating block E*. Figs. 4*a* and 4*b* show one way of arranging this block. One pair of wires thus brought to the terminals lead to the field magnet coils, and the current in this wire excites the field magnets. The other wires are used in series, or as required in the external circuit. The current for the field magnets passes through a commutator, H, and brushes, as shown. Figs. 5 and 6 show the parts *h h* of the commutator used to transform the alternate into continuous currents.

In order to provide exciting currents for the field magnets proportionate to the requirements of the bobbins, from which the currents are to be taken for illuminating or other purposes, the exciting bobbin which is connected with the brushes or rubbers H is coiled with wire of a gauge corresponding to the gauge of the wire on the field magnets, and the weight of this coil is made to correspond with the weight of the other bobbin coils of the armature. The conducting wires through which the exciting currents are passed to the field magnets are also made of equal gauge. By this means induced currents are passed into the field in the exact proportion required to give full efficiency to the field magnets.

In order to combine together two or more currents of the working circuits according to the work in hand, there is a forked sliding piece K (Fig. 4*c*), made to under-run the terminal screws fitted to the several blocks, and thereby to couple them up as required.

To avoid heating the armature, should the circuit be accidentally broken, a small electro-magnet (Figs. 7 and 8) is mounted on the fixed armature *e e'*. When the current passes normally into the lamp circuit the armature of this magnet is raised, but should the current, cease the armature falls and makes the contact necessary for its renewal.

THE TRANSMISSION OF POWER BY ELECTRICITY.*

BY LL. B. ATKINSON, ESQ.

(CONTINUED FROM PAGE 91.)

ERRATA.—In estimating the kinetic energy of water in the pipe ·25 should read ·166. In reducing the formula $\frac{1}{2} m v^2$, there is an error in the place of the decimal point. The final answer, instead of 14·7, should read ·066.

I think it will be best for me here just to apply these general remarks to the case of one machine. I shall choose the Gramme,

* A Paper read before the King's College Engineering Society. Printed by permission.

because I consider it the simplest, whilst it is typical of all others.

I have shown, in Figure 4, the principal parts of this machine. We have two magnet poles, north and south; between the curved ends of these there is an axle on which is mounted an iron ring, the iron being as soft as possible. This ring is wound with about eighty coils of wire, all continuous. In the diagram I have shown only one layer of wire; in reality it forms several layers. At intervals round the ring the insulating material is scraped off, and a short piece of wire soldered on. Each of these short pieces is brought to a separate slip of copper on the commutator, each strip being carefully insulated from its neighbour. There are generally about eighty slips, whereas for the sake of clearness I have only shown eight.

Now suppose the ring rotated in the direction of the arrow.

It will be seen that as any individual coil leaves the point A, more and more of the lines of force which proceed from one pole to the other, round by the iron ring, pass through the coil

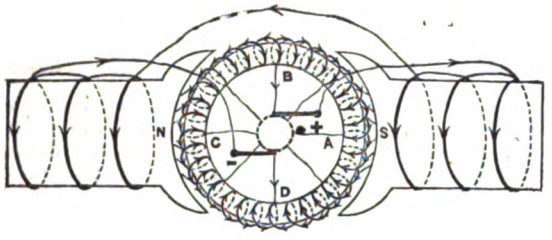

FIG. 4.

The effect of this will be to produce a current in the direction shown by the arrows on the coil. When the coil arrives at B it begins then to lose some of the lines passing through it; the effect is to produce a current, but in the opposite direction to that produced by the addition of lines, so here the current is reversed. We might follow the coil right round, but the action in the other half is precisely analogous, but inverted. Now, if we look at the arrows, we see that the currents in the two halves of the ring both proceed from D and meet at A. The result is that they make use of the short wires at these points to run down to the commutator slips, against which press metallic combs or brushes, connected with the exterior circuit. Owing to the number of strips there is always a strip in position to take off the current, and hence the action is continuous.

The direction of the current produced in any coil is, by Lenz's law, always in such a direction as to oppose the motion by its attraction or repulsion of the magnetic pole. Supposing the machine to have electro-magnets, we must allow the current pro-

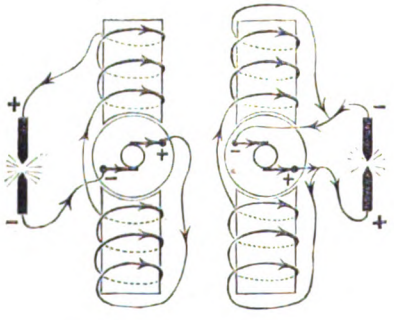

FIG. 5.

FIG. 6.

duced by the machine to circulate round the magnets. There are two methods of doing so.

Either the whole current passes through the magnets and then to the exterior circuit, lamp, motor, or whatever it may be, in which case the machine is called a series dynamo, or it branches on leaving the brushes into two separate circuits; part goes at once to the exterior circuit, whilst part is wholly occupied in keeping the magnets magnetised, in which case the machine is called a shunted dynamo (Figs. 5 and 6). Both methods have particular advantages for certain cases.

In order to transmit power by electricity we must have the following things:—1st. A source of power, as steam, water, wind, or whatever it may be; 2nd. An electric generator, or dynamo electric machine; 3rd. A conductor for the electricity between the two points; 4th. A receiver of power, either a motor or accumulators.

I shall not speak of the source. I shall suppose we have settled on some source of power.

We produce our electricity by a dynamo, preferably a shunted one, for reasons which will presently appear. At the other end we have our receiver, which I shall suppose a motor.

Every dynamo electric machine will, if a current be passed into it in the same direction as the current it produces when running flows, begin to revolve backwards and act as a motor. This is a consequence of what is known as Maxwell's rule, which states, "That any coil carrying a current will tend to place itself so that as many lines of force as possible are enclosed by it." Up to the present time all our motors have been dynamos thus reversed, though special motors are now being designed.

Every generator will act as a motor, but every motor will not act as a generator, though many will.

We can apply this motor to actuate any machinery we like, and hence we have here a true transmission of power. At one end we have our prime mover, at the other the electromoter giving out the power, or part of the power put into the whole system by the prime mover.

Now let us examine a little more closely into these individual parts. Of the power put in by the prime mover, a dynamo will give out nearly 90 per cent. electrically. To estimate the h.-p. given out electrically by any generator, we multiply the electromotive force in volts by the current produced, measured in amperes, and multiply the product by ·00134. This is the actual h.-p. given by the machine to the wire. Now, in going through the wire a certain part of this is lost, since a current passing through a wire always heats it, and heat means loss of energy, so rather less than this amount arrives at the other end. Here we have seen that the current sets the dynamo in motion, but we have seen that a dynamo in motion produces a current, and this current is in the opposite direction to that producing the motion. The effect is that the moment the motion commences the current is weakened. The electromotive force set up in the machine in opposition to the elecromotive force of the distant generator is called the back electromotive force. Now, curious as it may seem, if it were not for this back electromotive force, we could turn no part of our electrical energy into mechanical work. The only part of the energy which enters the machine, which produces any useful effect, is that part which is forced through the machine against the back electromotive force, all the rest merely serves to heat the machine. Suppose we send a current of A amperes through any conductor of R ohms resistance, the h.-p wasted in heat is

$$A^2 \times R \times \cdot00134.$$

Now, this would hold good just as much for the current passed into the dynamo as for any other case, and if the current is thus producing heat, it cannot produce mechanical work at the same time; but if we pass a current of A amperes through a machine of resistance R, and which is producing a back electromotive force e, the useful work in h.-p.,

$$e \times A \times \cdot00134,$$

the waste is $A^2 \times R \times \cdot00134$;

so the higher we make e the less is the loss in the machine.

Now let us look at the whole transmission similarly.

The generator produces an electromotive force E.

The motor produces a back electromotive force e. The electromotive force which will produce a curent is E − e the difference.

By Ohm's law, as I explained, the current is

$$\frac{E - e}{R} = A.$$

Now, the whole work given out by the generator is

$$A \times E = \frac{E - e}{R} \times E.$$

The work put into the motor we may, for the moment, assume to be equal to this. It will be rather less, in fact, if any considerable distance separates them. The useful work, that is, mechanical effect, of the motor is, as I just now showed,

$$A \times e = \frac{E - e}{R} \times e.$$

Now, in order that the transmission should be as efficient as possible, that is, that as large a proportion as possible of the work put in should be given out, we must make the following fraction have its greatest value:—

$$\frac{\frac{E - e}{R} \times e}{\frac{E - e}{R} \times E}.$$

We shall get the greatest value for this fraction when e is nearly equal to E.

If e nearly equals E, $\frac{E - e}{R}$ will be very small, but if E and e are themselves large absolutely, we can transmit any amount

Digitized by Google

of power we like. So in order to transmit power economically and efficiently by means of electricity we must use machines of very high electromotive force, and in this comparatively simple calculation lies the basis of the whole solution to the problem, as, I believe, was first pointed out by Professors Ayrton and Perry. Now, the conductor between two points must generally be of copper, which is very expensive, and hence we must use as small a wire as possible. Let us first see what is the smallest wire we can possibly use safely, without its getting too hot, then we shall see what is the *best* wire to use.

Let us suppose the wire to be hung in the air so as to have free access to the air and free radiation. We know from Newton's law that the amount of heat radiated where A = area, θ = temp. above air, is $\propto A \times x \times \theta$, or more generally the following law, due to Dulong and Petit.

$$m \times 1{\cdot}0077^{t} (1{\cdot}007^{T} - 1) \times A.$$

This gives the loss of heat per hour from a surface A square feet, when $T - t$ is the difference of temperature between the heated body and surrounding bodies, and t is the temperature of surrounding bodies, m is a constant differing for different materials. For copper its value is about 3·3.

It would not be wise to allow the wire to become hotter than 150deg. F. The temperature of the air averages about 55deg., so the difference of temperature between the air and the wire = 95deg. F = 35deg. C.

This calculation was inserted, not on account of any importance which I attach to the result, but rather to show the points on which such a calculation depend.

Formula for the minimum size of wire for any current.

$$\left.\begin{aligned} & 1{\cdot}0077^{t} (1{\cdot}0077^{T-t} - 1) \times m \\ &= 1{\cdot}0077^{12-7} (1{\cdot}0077^{35} - 1) \times m \\ &= 12{\cdot}7 \times {\cdot}0033313 (35 \times 0033313 - 1) \times m \\ & \quad {\cdot}04230751 ({\cdot}1165955 - 1) \times m \\ &= {\cdot}04230751 (1{\cdot}3079 - 1) \\ & \quad ({\cdot}13070) \\ &= {\cdot}0423075 + T\,{\cdot}4884097 = T{\cdot}5307172 \times m \end{aligned}\right\} \text{Calculation by logs.}$$

$= {\cdot}3394 \times 3{\cdot}31 = 1{\cdot}1233$ units of heat per foot surface per hour (pound water centigrade units)

The surface of a wire in sq. feet when l = length in miles d = diameter in inches

$$= \pi d \times l \times 5280 = \pi dl \times 440 = dl \times 1382{\cdot}3 \text{ sq. feet.}$$

The heat generated in any wire is $C^2 R \times \frac{1}{4{\cdot}2} = C^2 \times \frac{l}{20d^2} \times \frac{1}{4{\cdot}2} = \frac{C^2 \times l}{d^2} \times {\cdot}0119$ (gramme water centigrade units) per sec.

Since the surface of a wire is $dl \times 1382{\cdot}3$ sq. feet, the heat radiated is $1{\cdot}1233 \times 1382{\cdot}3 \times dl$ (pound water centigrade)

$$= {\cdot}0504958 + 3{\cdot}1910981$$
$$= 3{\cdot}1910981$$
$$= 1553{\cdot}7 \times dl \text{ units (lb. } H_2 0.C^0.)$$

to convert this into (grm. $H_2 0.C^0$) multiply by 453·6

$= 3{\cdot}1910981 + 2{\cdot}6566730 = 5{\cdot}8477711 = 704320$ (grm. $H_2 0.C^0$) per hour,

so heat generated is $\frac{C^2 \times l}{d^2} \times {\cdot}0119$ units per sec.

Heat radiated is $dl \times 704320$ per hour $= dl \times 195{\cdot}6$ per sec. And for the temperature to be constant these two must be equal.

$$\therefore \frac{C^2 \times l}{d^2} \times {\cdot}0119 = dl \times 195{\cdot}6 \therefore d^3 = \frac{C^2 \times {\cdot}0119}{195{\cdot}6}$$

$$d^3 = \frac{{\cdot}0119}{195{\cdot}6} = C^2 = {\cdot}000060838\ C^2$$

$$\therefore d = {\cdot}034364 \sqrt[3]{C^2}$$

Where d = diameter of wire. This is only strictly true in vacuo, in air about 50 to 100 per cent. more dissipation of heat will result.

We have now seen what is the possible limit to the thinness of the wire, but it does not follow that the *best* wire is of necessity the smallest. There are two considerations. If the wire be small we waste a considerable amount of power in heating the wire, and, if the power costs much, this will be an expensive item.

On the other hand, if we make the wire large we sink a considerable capital outlay, and hence we are losing the interest on this capital. In any case we lose something in wasted power, something in capital sunk. We must try to make the sum of these two losses as small as possible.

It is evident that a very considerable element in the calculation is the cost of power. If we use steam it may be expensive, if we use a waterfall the power costs next to nothing, and we do not care particularly how much we lose, and we then should use the smallest practicable wire, as I before explained.

Without going into the details of the calculation, I will give a general formula for the best size of wire for transmission of any amount of power at any cost per horse-power. The price of copper assumed is £70 per ton, and 5 per cent. interest allowed on capital outlay.

If cost of copper is not £70, we can alter this by remembering that the area is proportional to

$$\frac{1}{\sqrt{\text{cost of copper}}}.$$

The formula given by Sir W. Thomson at the York meeting of the British Association is $A = C\sqrt{\frac{e}{1{\cdot}38}}$, where A is area in centimetres, C is the current, $e \times$ £10 is the actual cost of a horse-power per year.

I have explained how essential to economical transmission is the use of high electromotive forces. Now, though this may seem simple, it involves various inconveniences. First, it would be fatal to touch the wires, thus completing the circuit; second, it makes the insulation of the line difficult. The second difficulty can be overcome by using insulating materials of very high quality, and putting the line up with great care. The first of these disadvantages makes it necessary that the power transmitted should not be at once used to light houses, work factory machinery, &c., where it would be used by ignorant persons; but that it should be received at a station, and converted into electric power, with a lower electromotive force. There are two ways of doing this. We may receive the power into a primary motor, which motor shall drive dynamos furnishing a lower electromotive force and a larger current. Such a system might be worked without much loss. Another way, due to Sir W. Thomson, is to charge accumulators, all arranged in series as Fig. 7.

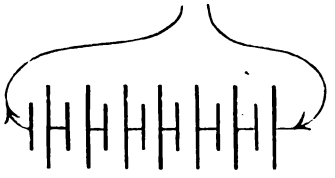

Fig. 7.

Then rearrange in parallel circuit as in Fig. 8, for discharge, the whole quantity of energy given out will be nearly the same, but

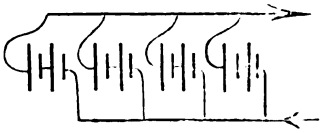

Fig. 8.

at a lower potential. In the one case the work put in will be $n\,E \times Q$. Each cell taking $E \times Q$, if arranged as in 2, the the work given out by each cell is $E \times Q$, therefore each pair will give $2\,E \times Q$, and so the whole set will give

$$2\,E \times \frac{n\,Q}{2} = n\,E\,Q.$$

Some people think this plan the more promising, but whether it can be efficiently done depends on what improvements will be made in secondary batteries.

In charging secondary batteries we have a back electromotive force, and all considerations with respect to the use of a receiving motor hold equally true for accumulators.

As I before stated, the efficiency of the transmission depends on the ratio of the back electromotive force to the primery electromotive force, or the ratio

$$\frac{e}{E}.$$

Since in dynamos and motors the electromotive force is proportional to the speed, that is, if the magnetic field is constant, the efficiency would depend on the ratio of the two speeds,

$$\frac{s}{S}.$$

An interesting experiment has been made at Munich. Power

Digitized by Google

is transmitted from Wiesbach to Munich, a distance of about 57 miles. There were used two ordinary telegraphic wires, 4½ millimetres diameter, one as lead and the other as return wire.

The total resistance of the circuit was 1,900 ohms. Two similar machines (Grammes) were used, their resistances being 470 ohms each, the resistance of the line being 960 ohms.

The speed of the first machine was 2,200 revolutions per minute, the speed of the second 1,500 revolutions per minute. From these speeds we should expect the efficiency to be

$$\frac{s}{S} = \frac{1,500}{2,200} = \cdot 67, \text{ or } 67 \text{ per cent.}$$

Actually about 60 per cent. of the energy put in to the wire at one end was got out at the other, the rest being wasted in heating. The amount of power transmitted in this case was not very large, nevertheless it is a case of great interest, owing to the use of ordinary iron telegraph wires.*

Perhaps, now, it will be well to take a few instances, and compare electricity and water, but here it may be remarked that whilst the pressure of water is limited by the weakness of pipes, the possible limit to the electromotive force which may be used is very high indeed.

The efficiency of water transmission is given by the formula

$$M = 1 - k\left\{\frac{E^2 \times l}{p^3 d^5}\right\}$$ where E is the h.-p., put in p the pressure, d the diameter of pipe, l the length.

The efficiency of electric transmission is

$$M = 1 - k\left\{\frac{E \times l}{V^2 \times d^2}\right\}$$ where V is the electromotive force of the generator, d diameter of wire;

k in each case is a constant depending on our units of length, &c.

It will be seen that the transmission of large quantities of power by water means great loss, by electricity not nearly so much, by water the efficiency increases as the cube of the pressure, but then the pressure cannot often be greater than 700lb, whilst the potential V may be as much as 80,000 volts.

Suppose we want to transmit power 10 miles, and we use a 6" pipe and 700lb. pressure, that is the almost highest pressure ever used practically. Then,

If we put in	1,000 h.-p.,	we lose	10 h.-p.
,,	2,000	,,	80 ,,
,,	6,000	,,	640 ,,
,,	8,000	,,	5,120 ,,
,,	10,000	,,	lose all.

Now, electrically, let us transmit 10 miles with a half-inch cable, using earth return; let the potential used be 3,000 volts; let us maintain at the receiving end a potential of, say, 2,000 volts. The resistance of such a line will be nearly 2 ohms.

$$E - e \quad C$$

The h.-p. transmitted $= 3,000 \times 500 \times \cdot 00134 = 2,010$ h.-p.
The h.-p. received at other end $2,000 \times 500 \times \cdot 00134$ 1,340.
The h.-p. lost $= 1,000 \times 500 \times \cdot 00134$ 670.

So, out of 2,010 h.-p., we lose 670 h.-p.

But, suppose we use 40,000 volts over similar conditions, and maintain a potential at the other end of 39,000, the current remains the same.

The h.-p. transmitted is 26,800.
The h.-p. received is 26,130.

The loss is 670 h.-p., just the same as for 2,010. So we may increase the h.-p. transmitted, and lose no more by merely increasing the working potential. This fact cannot be too clearly impressed on the mind. Many systems using a low potential are advertised for lighting and transmission of power; for this purpose they are wholly inadequate. I think now I have given a general notion of the method of action, and the conditions of efficient working in transmission of power by electricity. The advantages of all methods of transmitting power consist in generating power wherever it may be cheaply obtained, as with water power, or by large engines of several thousand horse-power, and then distributing, instead of each consumer working a small and inefficient steam engine himself. Even if we lose 50 per cent. in transmission we should still be the gainers by such a method of working, but I think we may look for a higher yield than this.

I have not entered in this paper into any details as to the best dynamos, the best motors, or anything of this kind, these alone would more than fill a paper; neither have I given any description of the methods of distributing from a central station, over a considerable area. This again would be too wide a subject to begin in the limits of this paper. What I have tried to do is to lay before this society the main bearings of the problem, to show what are the points to aim at, and to show the weak points of the system.

* Since this was written these results have been upset, it having been shown that, using similar machines, the magnetic fields would not be equal.

To sum up the advantages and disadvantages of this system, compared with water and ropes, I think that for work of a somewhat temporary character ropes might be used, but when continued use is contemplated, the expense attending repairs on this system would outweigh its advantages. Wherever we want to transmit a moderate amount of power over moderate distances, particularly for slow moving machinery such as punching or shearing machinery, or for riveting machines, water is at its best, and may advantageously be used.

But when we come to transmit large quantities of power for great or small distances for any rapid moving machinery, or for railways, or for lighting and heating, I think that no system will be found to successfully compete with the transmission of power by electricity.

[The author wishes to state that, having attended Professor Ayrton's lectures on transmission of power, he is indirectly indebted to him for much that is of value in the paper, and indirectly to Professor Perry, who has taken so distinguished a part in reducing the various systems to a *quantitative* comparison. It will be seen that the valuable store of information contained in Professor Perry's recent Cantor Lectures has been largely drawn upon.]

SLIP

JAMAICA AND COLON.—The cable between these two places, which was interrupted in the month of September, is now restored.

ELECTRIC LIGHT IN LIBRARIES.—Electric lights have been placed in the main room and newspaper room of the Mercantile Library of Philadelphia.

GREAT NORTHERN TELEGRAPH COMPANY.—This company announce a half-yearly interim dividend at the rate of 5 per cent. per annum, and payable on the 1st of January by Messrs. C. J. Hambro and Son.

UNDERGROUND WIRES IN FRANCE.—The underground cables between Paris, Lille, Nancy, and Dijon, have recently been opened for traffic with success. That between Paris and Lyons is to be opened shortly.

SWAN UNITED ELECTRIC LIGHT COMPANY.—This company have made a call of 10s. per share, payable on the 9th January, 1883. This call is made in order to carry out some important new installations now in hand.

ROYAL SOCIETY.—At the meeting of this society on Thursday, a paper "On the Connection between the State of the Sun's Surface and the Horizontal Intensity of the Earth's Magnetism," was to have been read by Professor Balfour Stewart.

WESTERN AND BRAZILIAN TELEGRAPH COMPANY.—The traffic receipts of this company for the week ending December 15th, 1882, were £2,732, after deducting the "fifth" of the gross receipts payable to the London Platino-Brazilian Telegraph Company.

LONDON PLATINO BRAZILIAN TELEGRAPH COMPANY.—The revenue of this company for the month of September, 1882, is estimated at £1,784 (Western Brazilian portion £1,340, land lines £444), as against £1,525 for the corresponding period of 1881.

SOCIETY OF TELEGRAPH ENGINEERS.—The *Journal* of the Society of Telegraph Engineers and of Electricians for December, is wholly, or almost wholly, devoted to Colonel Frank Bolton's paper on "Some Further Historical Notes on the Electric Light," &c.

NEW TELEGRAPH LINES IN FRANCE AND BELGIUM.—It is stated that France and Belgium have arranged to construct telegraph lines along the Sambre, Aisne, Scheldt, and Lys, in order to exchange despatches on any rise of those rivers threatening an inundation.

WEST COAST OF AMERICA TELEGRAPH COMPANY.—The coupons due on the 31st December next on this company's debentures will be paid on the 30th inst., on presentation at their bank, by Messrs. Barclay, Bevan, and Co. Coupons must be left three clear days for examination.

EASTERN AND SOUTH AFRICAN TELEGRAPH COMPANY.—This company notify that the coupons due on January 1st next on their Five per Cent. Mortgage Debentures will be paid on presentation by Messrs. Barclay, Bevan, and Co. Coupons must be left three clear days for examination.

A TELEPHONE CABLE.—News from America says the Southern New England Telephone Company have laid a 21-wire cable across the Thames River, from Winthrop Point to the Groton shore, thereby putting the States of Massachusetts, Connecticut, and Rhode Island on speaking terms.

MAXIM INCANDESCENT LAMPS IN MADRID.—The whole of the house occupied by the Minister of War at Madrid, is lighted by means of Maxim lamps. The current is supplied from the central station of the Sociedad Espagnola de Electricidad, which is situate close by. Gramme machines are used.

NEW LAND LINES.—*The Times'* Paris correspondent, telegraphing on Dec. 18, says:—"France and Portugal are in treaty for a land telegraph between Paris, Bordeaux, and Lisbon, which would be used for communications between northern and central Europe, and South America and West Africa."

EASTERN EXTENSION TELEGRAPH COMPANY.—The directors of the Eastern Extension, Australasia, and China Telegraph Company have declared an interim dividend for the quarter ended 30th September last of 2s. 6d. per share, or at the rate of 5 per cent. per annum, payable on the 16th proximo.

ELECTRIC LIGHTING ON SHIPS.—The "Aurania," a new steamer which is now approaching completion at the hands of Messrs. J. and G. Thomson, of Clydebank, and which has been built for the Cunard Steamship Company, will be lighted by electric light. Swan lamps will be used. They will be erected and fitted up by Messrs. Siemens Brothers.

ELECTRIC LIGHTING AT ROCHESTER (U.S.A.).—The Board of Aldermen of Rochester (U.S.A.) have contracted with the Brush Electric Light Company to maintain 48 arc lamps, at 45 cents. per lamp per night. It has been estimated by the board that the electric lamps will replace 325 gas lamps costing for light and maintenance 7,000 dollars per annum the estimated cost of the Brush lamps being 7,884 dollars per year.

ELECTRIC LIGHTING IN TRAINS.—The Pullman train to Brighton is now lit with 40 instead of 18 incandescent lamps, owing to the employment of the new Faure-Sellon-Volckmar accumulator supplied by the Electrical Power Storage Company. In the first instance 70 Faure accumulators (original pattern) were required for the 18 lamps, whereas now there are only 30 Faure-Sellon-Volckmar cells used for the 40 lights, their total weight being considerably less than half that of the cells originally employed.

EASTERN TELEGRAPH COMPANY.—This company announce the payment, on January 15th next, of a dividend of 3s. per share on the preference shares of the company, less income-tax, for the quarter ending on the 31st inst., and that an interim dividend of 2s. 6d. per share, with a bonus of 1s. per share, both free of income-tax, on the ordinary shares, in respect of profits for the quarter ended September 30, will be paid on the same date. The registers of transfers will be closed from January 8th to January 15th, 1883, both days inclusive.

ELECTRIC LIGHTING AT COVENT-GARDEN THEATRE.—The Metropolitan Brush Electric Light Company are engaged in setting up 24 Brush lamps in this theatre, in connection with the Christmas pantomime. Amongst other things, we believe that a Christmas tree will be shown, lighted by 50 incandescent lamps, the current for which will be supplied by a Schuckert dynamo machine. The arc lights will be fed from two 16-light Brush dynamos, driven by one of Fowler's compound semi-portable undertype engines. We shall hope to give further details of this work later on.

ELECTRIC LIGHTING IN BARCELONA.—Two cafés in Barcelona are lighted by means of Swan lamps, about 100 being used in each café. The current is generated in the works of the Sociedad Espagnola de Electricidad, situate in the Calle del Cid. The same company are erecting a central station at

Digitized by Google

10, Ramble de Cavalites, in this town, where eventually 200 horse-power will be available in the shape of four 50 horse-power gas motors for driving electric light machinery. At the present moment several Gramme arc lamps, distributed about the town, are worked from this station.

How to Take Portraits of Burglars.—A correspondent of a contemporary suggests a new use for electricity in connection with burglars. He suggests that instead of utilising a current to ring an alarm, it should be adapted "to turn on momentarily the full glare of an electric light, and at the same instant expose a plate in a camera all ready to take an instantaneous picture. The burglar, of course, will take to flight, but will leave his photograph behind. The same blaze of light which has alarmed him will awaken the sleeping inmates, who can proceed at once to the camera and secure the negative."

Electric Lighting for Brighton. — The Brighton Town Council have adopted the recommendation of their Gas Committee to the effect that a provisional order should be applied for to enable the whole borough to set apart a permissive area for the supply of electricity for public or private purposes, and to constitute a part of the centre of the town, bounded on the north by North-street, east by East-street, south by Junction-road and King's-road, and west by West-street, an area for the compulsory supply of electricity. It is stated that this latter will entail an outlay of £100,000.

Electric Lighting at Oxford.—The Union Club at Oxford have entered into a contract with the Pilsen-Joel and General Electric Light Company to light up their premises by means of arc and incandescent lamps. Six Pilsen arc lamps will be used, and 100 incandescent lights. The dynamo machines will be driven by a gas engine, for which a special house is to be built. The Union Club is the possessor of a good library, and we believe that the decision to use electric lights in place of gas has been come to in the hope of saving their books from the destruction to which the use of gas renders them liable.

Continuous Lighting.—With reference to our note of the continuous lighting effected by the Edison Company on Holborn-viaduct during the recent foggy weather, we may mention that the Maxim-Weston Company lighted Southwark Bridge, Queen-street, Queen-street-place, and Queen Victoria-street, with 32 Weston arc lights continuously from the Saturday afternoon until the following Tuesday morning. The rooms of the South Eastern Brush Electric Light Company at 110, Cannon-street, E.C., were also lighted during the foggy weather by incandescent lamps, the current being supplied by the B. T. K. storage system.

Electric Light in Washington (U.S.A.).—The art exhibit of the Garfield Monument Fair (opened on the 26th of November), is held in the rotunda of the capitol. It is lighted by eight Weston arc lamps of 1,200 candle-power each. The effect is very brilliant and pleasing, the lamps being suspended from one of the galleries high up in the dome. There are besides six more lamps in other parts of the fair, all fed from a 14 light Weston dynamo, driven by an engine used for running the ventilating apparatus of the Senate Chamber. The plant is under the able management of Mr. N. W. Ellis, superintendent of the U.S. Electric Lighting Company of Washington.

Electric Lighting in London.—The Mile End Old Town Vestry have received a report from their Special Committee on the Electric Lighting Act. In this report the Vestry stigmatise the Act as "one of the most extraordinary character ever passed by Parliament, for, beyond a few general provisions, the whole matter of details is left in the hands of the Board of Trade." They also think the "knowledge of the science of lighting by electricity is small." Altogether, the Mile End Old Town Vestry's report is not favourable to electric lighting. And yet, if we are not mistaken, it was this same committee who were blown about in promiscuous fashion a few weeks back by an explosion of gas in the identical room where they were concocting this report.

Electric Bells for Prisons.—Since Lancaster Castle has been converted into a military prison great inconvenience has been experienced owing to the mechanical signals from each cell getting out of order. To avoid this, and in order to establish a reliable system of signals between the different officers of the prison, Mr. Sharples, electrician, of Preston, was instructed to devise and establish a system of electric signals. This has been done, and the work completed. It was, however, a somewhat difficult task, as may be gathered from the fact of the walls being in many places three yards thick. Over ninety of the cells have each been fitted with an electric bell push, so made and arranged that the prisoners cannot possibly damage it. The pushes communicate with an indicator in the chief warder's office, the different warders' offices being also connected with each other by electric bells.

Electric Lighting from Batteries.—Electric lighting on a large scale by means of batteries has recently been carried out in Paris. The Compoir d'Escompte is lighted by 50 arc lamps, Siemens and Gravier's, and 100 Swan lamps, the current being supplied by Jarriant and Grenet's bichromate batteries. The reason for employing this antiquated means of carrying out the lighting of the place is stated to be because no engine or gas motor is allowed on the premises for fear of fire. There are 60 batteries of 48 cells in use, each feeding an arc lamp or a group of from 8 to 10 incandescent lamps. The E.M.F. of each battery of 40 cells is about 82 volts, and the current 24 amperes, Messrs. Jarriant and Grenet estimate that each battery in full work develops energy equal to one and a half horse-power. The liquid in the batteries is renewed by special compressed air apparatus and numerous pipes.

Glasgow College of Science and Arts.—The prizes &c., gained by the students at this college were distributed a few days since by Mr. David Rowan. In the technological examinations of the City and Guilds of London Institute, Mr. James, Livingstone, telegraphist, General Post Office, obtained first-class honours in telegraphy, and Mr. George C. Douglas in mechanical engineering. Mr. William T. Calderwood (draughtsman, Messrs. Mirrlees and Watson) was first in the United Kingdom in pass grade of mechanical engineering, and was awarded £3 and the silver medal. Mr. James Law Crawford, electric-engineering student, was third in electric lighting, and obtained £2 and bronze medal; and Mr. D. M. Fletcher second-class honours in both practical and theoretical chemistry. The proceedings were closed by a few encouraging and congratulatory words from the principal of the college (Mr. A. Jamieson).

The Late Crystal Palace Exhibition.—Considerable impatience has been felt of late by exhibitors at the recent Electrical Exhibition in the Crystal Palace who had been awarded diplomas and medals, at the non-receipt of the same and the seeming apathy of the authorities in regard to the matter. Upon inqury a few days ago at the Crystal Palace, the secretary, Mr. W. Gardiner, stated that it had been the intention of the management to distribute the awards on the occasion of the opening of the present International Gas and Electric

Digitized by Google

Exhibition on the 13th inst., but they had finally concluded to appoint a special evening therefor. He further stated that a diploma would be presented to each recipient of a medal. The prizes, which consist of diplomas of honour, gold, silver, and bronze medals (accompanied as stated by a diploma), are now ready, and the distribution, which will take place in the Palace, will be announced at an early date.

A WANT SUPPLIED.—In Mr. Preece's recent paper on Electrical Exhibitions, given in the *Journal* of the Society of Arts for the 15th inst., a new name will be found for a society which, not so long ago, was much perturbed as to what should be its appellation. The title given it by Mr. Preece (or the printer's devil), though peculiar, has, on the whole, an air of fitness about it, which no one will deny when he reads it in the light of certain events in the society's history. Mr. Preece is not unknown as a humorous and jocular lecturer of the first order, but his last joke is, so far as we know, his best, that is, if it really is his. Any one who will glance at the above mentioned issue of the *Journal* of the Society of Arts, p. 85, first column, immediately above the discussion on Mr. Preece's paper, will read "Society of Telegraph *Eccentricities* and Electricians," this being, we suppose, the latest effort to give the society a name which shall worthily represent it.

ELECTRIC LIGHTING IN THE COUNTRY.—The Town Councils of Liverpool and St. Helens have resolved to abandon their applications for provisional orders to supply the electric light in those boroughs.—The Sheffield Town Council have had their order prepared, but do not quite like having to "pay the piper." The Mayor has expressed his willingness to find the necessary money out of his own pocket. So far as we know, no decision has yet been arrived at on the matter.—The Jarrow Town Council have postponed the subject of electric lighting altogether for the present.—The Keighley Town Council will apply for a license, but not for an order.—The Bootle (near Liverpool) Town Council will apply for an order.—The Harrogate Improvement Commissioners have referred the matter to their Lighting Committee. Harrogate is supplied with gas by a private company.—The Knaresborough Improvement Commissioners will not apply for an order, and will oppose everybody else.

THE TELEPHONE IN LANCASHIRE.—The county justices of Lancashire have decided to connect the different wards, doctors' houses, &c., of the county asylum at Whittingham by telephone. This, the most modern asylum in the country, has about 2,000 inmates. Eight Gower-Bell telephones are to be used, the lines all converging to a central station, worked on the telephonic exchange system. The magistrates have instructed Mr. G. Sharples, electrician and telegraph engineer, of Preston, to carry out the work. It may be mentioned that Mr. Sharples some time since fitted up the county offices of Lancashire with telephones, electric signals, lightning conductors, and the large Record Room with twelve self-acting fire alarms, and also connected these offices, the county court offices, and the Sessions Court by three separate wires with the Preston Telephonic Exchange, of which he is the proprietor. This means of communication has been found a great convenience, as the Sessions Court is about one mile distant from the County Offices. Most of the other public buildings in Preston are also connected with this exchange, which has a large number of subscribers.

THE EDISON LIGHT IN MELBOURNE.—A recent issue of the *Melbourne Herald* contains an account of an exhibition of the Edison system by Major Flood Page, from which we extract the following. The exhibition was given in the Café Gunsler, Melbourne, where a dining room was lighted by Edison lamps. Our contemporary says:—"The tables, which were tastefully decorated, held bouquets, in each of which an Edison burner was placed, and the effect of the light shining through the petals was singularly beautiful. Two rows of lights, each of 10 burners, hung against the mirrors at the sides of the room, and two festoons of flowers, each holding 10 burners, crossed the room at either end of the tables. A cluster of five burners surrounded each of the ordinary chandeliers. Thus there were 50 lights in all, the result being a blaze of light which, had it been created by the combustion of gas, would have been absolutely unbearable. As it was, no one was affected by it, except in a very satisfactory fashion, for gentlemen who ordinarily find themselves compelled to use eye glasses, proved perfectly able to read an ordinary letter without them. Four gentlemen testified to this fact."

ELECTRIC LIGHT IN SYDNEY.—The *Sydney Morning Herald* office has been illuminated by the Edison electric light. In announcing the fact the *Herald* says:—"Wires at present are distributed over the composing frames and in the engine room, but the usurpation of the realm of gas has been so hasty that the shades were not properly adjusted, and hence the full value of the invention could not be apprehended. Enough, however, was seen to fill every one with admiring surprise, shadows being 'conspicuous by their absence.' . . . The difference in the temperature of the composing room, ordinarily very warm, during the time these lamps were burning was very marked. The order for the fittings was carried out by Mr. H. H. Kingsbury, representing Mr. Edison's interests in New South Wales. . . . Mr. Kingsbury had the whole of the paraphernalia fixed up, and, with the assistance of Mr. Patterson, engineer, the shafting adapted to the motor, in a very short space of time, without disturbing the routine of the establishment. The compositors, it may be mentioned, expressed their admiration of the new light, considering it superior to that to which they have hitherto been accustomed."

ELECTRIC LIGHT IN INDIA.—The opening of the Sirhind Canal at Rupar on the Sutlej by H.E. the Viceroy of India afforded to the Eastern Electric Light and Power Company an opportunity of displaying an installation consisting of both arc and incandescent lighting such as has never been seen in India. The camps of the Viceroy, the Lieutenant-Governor of the Punjaub, the civil and military, and the native chiefs were brilliantly illuminated by 48 Brush arc lamps of 2,000 candle-power each from the 22nd until the 26th November, and the reception and dining tents of the Viceroy were lighted by 36 Lane-Fox incandescent lamps of 20 candle-power, causing intense astonishment in the minds of the many thousand natives who crowded nightly round the engines and dynamos employed in the working, so much so that police had to be employed to keep them back. On the night of the 24th the current used for the lighting of the incandescent lamps was transmitted to lamps lighting the railway station for the departure of H.E. the Viceroy. As soon as his train left, the current was returned to his camp. The necessary power was supplied by three 16-light Brush dynamos, driven by portable engines.

THE BRUSH ACCUMULATOR.—Rumour has for some months been associating Mr. Brush's name with an accumulator, and we now have some definite news of the matter in the shape of the following telegram from the *Standard's* New York correspondent. The message was sent on Tuesday night, and runs as follows:—"The inventor of the arc light in the Brush exhibition claims to have solved the problem of the storage of electricity upon a commercial basis. His accumu-

Digitized by Google

lator supported thirty Swan incandescent lights for six hours. It measures 10ft. long, and the ends are 18in. square. The accumulator was charged from the circuit for supplying the street lights while they continued to burn. Automatic mechanism stopped the current when the process of charging was complete. The accumulator had absorbed ten amperes of current when it was full. Its lighting efficiency, per horse-power of steam, was twenty-nine candles. This accumulator requires only one-third of the space taken by Faure's; while it gives the same results in regard to polarisation. Whether the current will overcome the durability of the plates is not decided; but it is believed that the solution which separates the plates is not destructive. I can only testify that the lamps burned, and that there is no apparent reason to question the inventor's claims. Mr. Edison announces his charges for supplying the electric light to houses at the rate of two dollars for one hour's light equal to 2,000 candles. This is equivalent to gas at two dollars per 1,000 cubic feet." Pending the receipt of further information from America, we advise our readers to take the major part of this message *cum grano salis*.

THE EDISON LIGHT AT BRUNN.—A correspondent writes:—"Yesterday morning (Sunday, December 17), at 12 o'clock, there arrived in Brünn, by special train, some 200 members of the Engineers' Club of Vienna. Their object was to inspect the Edison light system. They were met at the railway station by the Bürgermeister, G. Winterholler, the city engineers, Mr. Ross, who is the agent for the Soc. Electrique Edison in Austria, and Mr. Jehl, in charge of the Brünn lighting arrangements. After breakfasting in the station they proceeded to the theatre. The auditorium and stage lights only were in operation. Everything was shown to them, the regulator, its operation, showing how each individual line could be operated, one, two, three, or more at the same time, or all of them together. The application of Edison's safety cut-out was also shown and explained, the main switch and cut-out which is in the cellar of the building and controls the stage and the other part of the house, the rooms, halls, &c. From the theatre they went to the machine room, and saw the dynamo machines, steam engine, &c., in operation. As each engineer left the room he was presented with a drawing showing the arrangement of the machines and engines. The speculations as to how the electricity was developed were amusing, some ascribing it to the friction of the brushes on the commutator, and so on. What puzzled some of them most, however, was the absorption of power. They could not conceive a bobbin revolving, and taking 8, 10, 20 horse-power as the case might be. After viewing the machines they went back to the theatre and witnessed the afternoon performance, which they much appreciated. In the evening they were entertained in the 'Turn Halle,' returning to Vienna about 9 p.m."

PROFESSOR HENRY DRAPER.—America has suffered a great loss in the death of the distinguished scientist, Professor Henry Draper, which occurred recently at his residence in New York. His death, at the age of 45, was altogether unexpected. A few evenings previous to his demise he entertained the members of the National Academy of Sciences, and immediately afterwards complained of pains in the chest. These developed into pleurisy, and made such rapid progress that death resulted a few days after. Professor Draper, who was the son of the late Professor John Draper, was born in the State of Virginia, and graduated from the Medical Department of the University of the city of New York in 1858, after which he spent some time in Europe visiting and studying places and instruments connected with scientific investigation. He held a number of positions of high public distinction, but resigned them early this year, as they interfered with his original researches. He made at Hastings, on the Hudson, the largest telescope in the United States—an equatorial telescope of 28in. aperture, whose construction has been justly described by President Barnard as "probably the most difficult and costly experiment in celestial chemistry ever made." His work on the grinding and polishing reflecting mirrors and methods of testing them is a standard volume to this day. His laboratory connected with his private residence in New York was one of the best equipped in the world, being fitted with the most refined and costly apparatus, much of which was his own invention and construction. His astronomical successes were innumerable. He was connected with the Commission of 1874 to observe the transit of Venus, and received a special gold medal for his labours, struck by the United States Mint by order of the Government. His wife, a daughter of Cortlandt Palmer, whom he married in 1867, was his most competent and enthusiastic assistant in his scientific work.

INFLUENCE OF TEMPERATURE ON MAGNETISATION.—M. Bersen has studied the influence of temperature on the magnetisation of iron, steel, nickel, and cobalt. He places the bar to be experimented on in a constant magnetic field, at different temperatures, and compares its magnetic moments. To make this comparison he adopts the method of Gauss. His apparatus consists of a Bunsen battery of from six to ten cells, the current from which, after having passed through a commutator, traverses a retort carbon rheostat, then the coil which serves to produce the magnetic field. A galvanometer placed in a shunt enables this current to be kept constant. In this magnetising coil is placed the bar, which causes a small declination needle, suspended by a thread to the interior of a copper cage, to deviate. The deviations are read by means of a mirror and scale. The magnetising coil, which must be capable of withstanding high temperatures, is composed of a wire wound without permitting the coils to touch, on a glass core, and covered with plaster. The whole is placed in a copper stove and heated by a gas lamp. The temperature, which is maintained constant as long as possible, is measured by a thermometer thrust into the stove. Some of the results obtained are as follow:—As regards iron, magnetisation is nearly independent of temperature. The total and temporary magnetisations increase up to 260deg., then they decrease, whilst the permanent magnetisation diminishes very slightly. With steel, the total magnetisation increases at first, attains a maximum at 260deg., and then decreases; the permanent magnetisation attains its maximum towards 240deg. Variations of temperature during the experiment exercise an influence on the magnetisation, which increases under these conditions. If the temperature of a bar magnetised when cold be raised, its magnetisation diminishes; the same occurs if a bar, which has been magnetised when hot, is cooled. If, now, we temper this latter it retains a greater magnetic moment than if it had been worked at a low temperature. With nickel, the total magnetisation slowly increases up to 240 degrees, and after reaching 280 degrees decreases very rapidly, becoming *nil* at about 330 degrees. Nickel magnetised at a low temperature and heated to 330 degrees loses all magnetisation; if, on the other hand, it has been magnetised at 280 degrees, and subsequently slowly cooled, its magnetic moment begins at first to increase, then decreases at about the ordinary temperature, but finally remains greater than at the temperature of magnetisation. Cobalt behaves like steel.—*La évue Industrielle.*

ELEMENTARY ELECTRICITY.

IV.

As before stated, the object of an electroscope, or electrometer, is the detection of difference of potential between the bodies to which its electrodes are attached. The amount of charge upon the bodies is not registered directly by the instrument, but in some cases the amount of charge on a conductor can be determined by an electrometer, though this implies a knowledge of the *capacity* both of the conductor and of the electrometer itself. This will be better understood when electric capacity has been considered.

The action of the gold leaf electroscope may be illustrated by the following experiments. In the instrument employed a wire gauze cylinder should be placed surrounding the leaves, and connected with a wire which passes through the stand of the instrument. The diameter of the cylinder should be such that if the leaves diverge very widely they may touch the gauze, and thus become discharged before they incur the risk of being torn. Let the electroscope be placed on an *insulating stand*.

Exp. I.—Connect the wire gauze to the earth by fastening the wire attached to the gauze to a gas-pipe. Now bring a small brass ball, which has received a positive charge from an electric machine, near to the plate which forms one of the electrodes of the instrument. The leaves will diverge, but if the ball be removed they will collapse again. On bringing the ball nearer they will diverge still more, and if the ball be made to *touch* the plate and be then removed the leaves will remain diverging. The leaves are now charged with positive electricity. If a negatively-electrified body be brought near the plate of the electroscope the leaves will tend to collapse, but if a positively-electrified body approach the plate the leaves will diverge still more. We are thus furnished with a means of determining whether it is positive or negative electrification which is causing the leaves to diverge.

Exp. II.—Detach the wire from the gas pipe and connect it with the plate of the instrument, thus making a metallic communication between the gold leaves and the wire gauze, but leaving no communication between any part of the instrument and the earth. Connect the plate with the prime conductor of an electric machine, and charge the instrument as strongly as possible. *No divergence* of the gold leaves will take place. (This is, of course, consistent with the statement that there is no electrification upon a conductor which is placed inside a closed hollow conductor, and is in electric communication with it.)

Exp. III.—The instrument being charged as in Experiment II., by means of a glass rod, or pair of pincers with insulating handles, remove the connection between the plate of the electroscope and the prime conductor of the electric machine; then break the connection between the gauze cylinder and the plate, and connect the gauze cylinder with the earth. So long as the wire connected with the cylinder remains insulated no divergence of the leaves will take place (if there be no leakage from the wire) but on making the earth connection the leaves will diverge violently and discharge themselves by touching the gauze cylinder.

Exp. IV.—Repeat the charging of the apparatus as in Experiment II. Then, having disconnected the electric machine, break the connection between the gauze cylinder and the plate, and, keeping the *cylinder* insulated, connect the plate to the earth. The leaves will again diverge and touch the cylinder. In this experiment the leaves diverge, although they are in connection with the earth, the gauze cylinder being insulated.

If in Experiments III. and IV. the instrument be only slightly charged, so that the leaves do not discharge into the gauze cylinder, but remain diverging when the cylinder or plate is put in connection with the earth, we may determine, as in Experiment I., whether the leaves are positively or negatively electrified. In the case of Experiment III. we shall find that the leaves are positively electrified, and in the case of Experiment IV. that they are negatively electrified, but in the latter case we must remove the earth connection from the plate before bringing up the electrified body which is to determine with what kind of electrification the leaves are diverging.

The results of the preceding experiments are easily explained if we remember that an electroscope indicates simply the difference of potential between the conductors connected with its electrodes, or, which is the same thing, the difference of potential between the gold leaves and the gauze cylinder. When these are connected, as in Experiment II., they are at the same potential, and no matter how high or how low that may be, no divergence of the leaves will take place. When, as in Experiment III., the cylinder is disconnected from the leaves, and put to earth, the potential of the cylinder is reduced to zero, while that of the leaves and plate remain high (though not so high as before the cylinder was put to earth), and the difference of potential of the leaves and cylinder is now made manifest by the divergence of the former. When, as in Experiment IV., the gold leaves are put to earth, the cylinder remaining insulated, the potential of the gold leaves is reduced to zero, while that of the cylinder remains high. The leaves then diverge so as to indicate the difference of potential between themselves and the surrounding wire gauze, and the leaves being now at a lower potential than the cylinder, their electrification is *negative*. These experiments, therefore, teach that the electroscope indicates difference of potential between the leaves and the wire gauze, and that both may be raised to the *same* potential, however high, without any indication occurring.

When the electroscope is used to measure the excess of the potential of a conductor above that of the earth, the wire gauze cylinder should always be connected with the earth, if possible by means of a gas or water pipe.

Coulomb's *proof plane* is a small piece of thin metal, mounted on an insulating handle, and shaped so as to fit accurately the portion of the surface of the body to which it is intended to be applied. It is, therefore, very seldom that it is really *plane*. If such a proof plane be applied to the surface of an electrified body it becomes virtually a part of that surface, and electrified in the same way as the surface it covers was before the application of the proof plane. If the proof plane be then carefully removed from the surface so as to break contact at every point at once, it will carry away just the amount of electrification which existed originally on the part of the surface which it covered. As no electricity can remain within a closed, or practically closed, conductor, it follows that no electricity can exist on the portion of the surface beneath the proof plane or on the lower surface of the proof plane itself, either while the "plane" is resting on the body, or when it has been removed only to a small distance from the surface. Hence the "plane" will carry away only as much electricity as originally occupied the portion of the surface covered by it, though this will spread over both sides of the proof plane when it has been removed far enough from the influence of the electrified body. If we are furnished with proof planes, and an electroscope, the gold leaves of which are diverging with a small charge of positive electricity, we can test the nature, and can roughly test the amounts of electrification on any portion of a surface to which the proof plane is applied.

On Electric Accumulators.

Exp.—Take two plane metal discs, A and B, supported on insulating stands, and let A be charged positively by an electric machine, and then insulated. Now bring B up so as to be very near to A, and parallel to it, and let the electrification of each side of B be tested with the proof plane. It will be found that the side of B which is nearest to A is negatively electrified, while the opposite side is electrified positively to the same extent. This electrification of B is an example of electrostatic induction. Now place B in communication with the gold leaves of an electroscope by means of a wire, the gauze cylinder being "put to earth." The leaves will diverge, and if the connection between the leaves and the plate B be now broken, and the electrification of the leaves be tested, it will be found that they are positively charged, indicating that the plate B is at a potential above that of the earth. If the wire connecting the gold leaves of the electroscope with the plate B be made

Digitized by Google

to touch either side of B the result will be precisely the same—the electrification of the gold leaves, and, therefore, the indication of the electroscope depending only on the *potential* of B and not on the electrification of the particular point to which the wire is attached. Thus, the proof plane serves to detect the *electrification of the surface* to which it is applied; the electroscope deals with the *potential of the conductor*. If A be connected with the gold leaves they will diverge somewhat more than when B is so connected.

Now, let the plate B be connected to the earth for a short time, and then tested as before. The side nearest A will now be found to be negatively electrified, and more strongly so than before, but the side remote from A will be *unelectrified*. On connecting the plate B itself with the electroscope no divergence will take place, indicating that B is at the same potential (zero) as the earth, which must clearly be the case when B is connected with the earth. If the plate A be now examined by means of the proof plane it will be found to be positively and very strongly charged on the side near to B, but to possess only a very feeble positive charge on the other side. On connecting the plate A with the gold leaves it will be found that it is still at a positive potential, but at a very much lower potential than it possessed before B was put to earth.

If, before B was brought near to it, the plate A was charged as strongly as was possible with the electric machine employed, then, when B is very near to A and in communication with the earth, the same electric machine will be found capable of increasing the charge of A till it is many times as great as it was before B was introduced. This is due to the fact, which we learned just now, that the potential of A is very much reduced by the negative charge induced upon B, and in order to raise A again to the potential of the prime conductor of the machine, notwithstanding the negative charge on B, which increases in the same ratio as the charge on A, it is necessary to increase the charge on A in a corresponding ratio. Thus, if the presence of B reduces A to a potential only one-tenth of that which it previously possessed, then in order to raise A again to its original potential, while B is kept connected with the earth, its charge must be increased ten-fold.

Two plates, such as we have described, one of which is insulated and the other connected to the earth, form an electric *condenser* or *accumulator*. The amount of electricity necessary to raise the plate A to the potential of the prime conductor of the electric machine will be greater the nearer the condensing plate B is made to approach to A. The only limit to the approach of B is determined by the passage of a spark between the two plates when they are brought very near to each other.

In the experiments just described the plates of the condenser should be very large in comparison with the parts of the electroscope. A quadrant electrometer may be substituted for the electroscope, and this will have the advantage of showing at once whether the potential of the body connected with it is positive or negative, as well as measuring the numerical value of the potential, but in this case a very feeble source of electrification must be employed.

Def.—The *capacity* of a conductor is the number of units of electricity required to charge it to unit potential.

The capacity of a conductor depends partly on its own size and shape, partly on the nature of the dielectric in which it is placed, and partly on its relations to other conductors.

When a body is removed from the action of all other bodies, it is said to be *isolated*.

The capacity of an isolated body depends only on its own size and shape, and the nature of the dielectric surrounding it.

In the case of a condenser, the capacity of the receiving plate A may be enormously increased by the proximity of the condensing plate B. The capacity of the receiving plate, when the condensing plate is put to earth, is called *the capacity of the condenser*.

If a plate of glass, sulphur, shellac, ebonite, paraffin, or any other solid or liquid dielectric be introduced between the plates of a condenser without changing the distance between the plates, the capacity will be found to be greatly increased.

Def.—The ratio of the capacity of a condenser having any substance for its dielectric to that of an otherwise equal condenser which has air for its dielectric is called the *specific inductive capacity* of the substance.

The differences between the specific inductive capacities of dielectrics are due to the fact, previously mentioned, that the repulsion (or attraction) between two given charges of electricity separated by a given distance depends on the nature of the dielectrics being less in solid or liquid dielectrics than in air. If K denote the specific inductive capacity of a dielectric, then the quantity of electricity which acting on an equal quantity at unit distance repels it with unit force, will be proportional to $\sqrt{K}$, and this will be the proper unit of electricity for experiments conducted in this particular medium. Thus the unit of electricity corresponding to a medium whose specific inductive capacity is K will be $\sqrt{K}$ times the ordinary, or air, unit. The unit difference of potential is the difference between the potentials of two points, in virtue of which the unit of work is done on the unit of electricity in passing from one point to the other. If the unit of electricity be increased the unit difference of potential will be decreased in the same proportion, so that the unit difference of potential corresponding to a medium whose specific inductive capacity is K will be $\frac{1}{\sqrt{K}}$ times the ordinary, or air, unit. The capacity of a condenser measured in terms of the units properly belonging to its own dielectric depends only on the geometrical relations of the conductor; but, to express this capacity in ordinary, or air, units, we must multiply by the factor K, since the unit of electricity referred to is $\sqrt{K}$ the ordinary unit, while the unit difference of potential employed is only $\frac{1}{\sqrt{K}}$ of the ordinary unit.

The Leyden jar is an example of the electric accumulator. It was first discovered accidentally by Cuneus, who endeavoured to give a charge of electricity to a quantity of water contained in a phial by sending sparks from an electric machine into the water by means of a nail which passed through the cork of the phial and dipped into the water within. The phial was held in one hand during the charging, and the nail was then touched with the other hand, when a severe shock was felt. In this case the water acted as the receiving plate, and the hand which held the phial as the condensing plate, the glass serving as the dielectric. The hand being in communication with the earth, all the conditions necessary for the operation of the condenser were fulfilled, and a very strong charge was, consequently, accumulated, glass having the advantage over air not only of a very great specific inductive capacity but also of a great electric *strength* or ability to resist a disruptive discharge taking place through its substance, so that the plates of a condenser when separated by a plate of glass may be much nearer to one another, for the same difference of potential, than when air is the dielectric.

The Leyden jar, as generally constructed, consists of a glass bottle, lined inside and outside with tin foil to about two-thirds of its height. It is generally closed by a wooden lid, through which passes a brass rod, terminating above in a knob and communicating below with the inner coating of the jar by means of a brass chain or otherwise. To charge the jar the outer coating or armature is connected with the earth, so as to form the condensing plate, while the inner coating is put in communication with the source of electricity. If, after charging the jar, a metal rod be connected with the outer coating, and one end of it made to approach the knob, which is in communication with the inner coating, a little before contact occurs a violent discharge will take place, producing a spark across the interval between the metal bar and the knob, and leaving the jar almost discharged.

Condensers are now made of very great capacity for use in submarine telegraphy. These are generally constructed of plates of tin-foil separated from one another by sheets of paper which have been saturated with melted paraffin. The alternate tin plates are connected together so that the first, third, &c., plates are connected with one electrode of the con-

Digitized by Google

denser, and the second, fourth, &c., plates with the other electrode. Standard condensers are sometimes made with plates of mica instead of paraffin paper for the dielectric.

THE (ELECTRIC) CONDUCTIVE AND INDUCTIVE CIRCUITS GEOMETRICALLY ILLUSTRATED.

BY F. C. WEBB, M.I.C.E.

(CONTINUED FROM PAGE 105.)

Before leaving this subject, it will be well to illustrate a few cases where, having a certain battery and the means of adding on another similar battery, we may add the second battery so as to obtain the greatest increase of the current. In the first place, if the external resistance is equal to the resistance of the battery, then, if we add the second battery on in series so as to double the resistance of the battery, and double also its electromotive force, we obtain the same current as when, by placing the second battery in parallel circuit with the first, we halve the resistance of the batteries, whilst maintaining the electromotive force constant. This is seen in Fig. 32, where B C is the resistance of a battery equal to A B, the external resistance, and C E, the E.M.F. Then A E is the potential line. If now we add on a similar battery in series, then the resistance of combined batteries becomes B G (double B C). The E.M.F. becomes G H (double C E), and the potential line becomes A H, which shows an increase of current. If, instead of placing the second battery in series with the first, we place it in

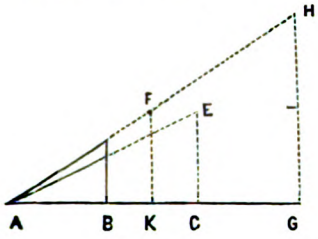

FIG. 32.

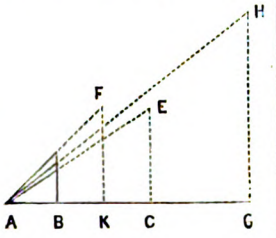

FIG. 33.

parallel circuit, then the resistance of combined batteries becomes half what the single battery was, and the combined resistance is B K, and the E.M.F. remaining the same as with the single battery, we get F K for the E.M.F. Now since A B = C B, and B C is bisected at K, A K is equal to half A G, and as also F K is half G H, we have A K : F K :: A G : H G, and as K F is parallel to G H, F must lie in a straight line between A and H; or, in fact, we have the same current whether we place the batteries in series or parallel. If the external resistance is less than battery, then placing the second battery parallel we obtain greater increase than if we had placed it in series with the other, as seen in Fig. 33, where the same lettering applies, the point F now falling outside the line A H, showing that the potential line A F, which is that obtained with the batteries in parallel circuit, is steeper than A H, which is that obtained with the batteries in series. If the external resistance is greater than the battery, then in the same way it will be seen by Fig. 34 that it is best to put the second battery in series, for here the potential line A H falls outside the point F, showing that there is a greater increase of current by placing the two batteries in series than by placing them parallel.

We will now see how the line of potential in a circuit is altered by branch conductors.

It has been proved by mathematicians that the joint resistance of two conductors in parallel circuit is a fourth proportional to their sum and the two resistances. Thus, if we have two resistances a and b, then if they are joined in a parallel circuit we have $a + b : a :: b : x$ (the joint resistance), or $\frac{a \times b}{a + b}$ = joint resistance. This can be projected geometrically thus:—Suppose A B (Fig. 35) a resistance, and A D another, added in parallel circuit, attached to the pole of a battery of a resistance A L and E.M.F. = L E. Then, if A D did not exist, the potential line would be E B, giving a potential at the battery pole A of A P. Now, suppose A D added. Mark off D', making D' A = A D. Erect a perpendicular at D', and cut off D' D'' equal D' A. Erect a perpendicular A C at A, and join D'' B, cutting A C at F. Then A F is the fourth proportional to A B + A D, A B, and A D. For we have B D' (= A B + A D.) : D' D'' :: A B : A F. If now we make A K equal to A F, then the total resistance of the circuit is L K, and joining E K, cutting A P at O, we get A O as the

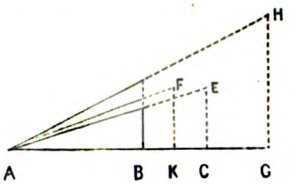

FIG. 34.

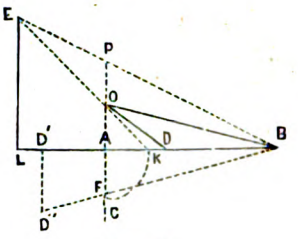

FIG. 35.

potential at the battery pole. Joining now O D, we get the line of potential in A D, giving for current in A D, $\frac{A\ O}{A\ D}$ and joining O B we get the line of potential in A B and

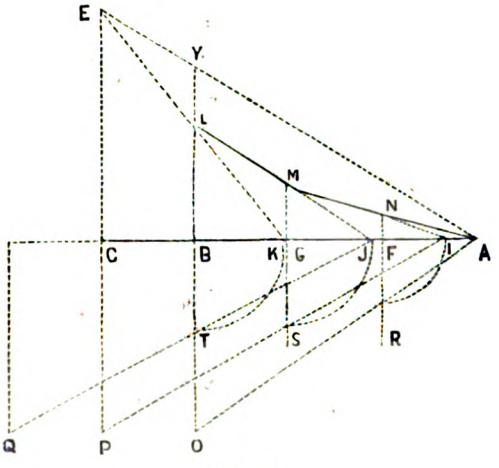

FIG. 36.

$\frac{A\ O}{A\ B}$ as current in A B, the total current in the circuit being $\frac{L\ E}{L\ K}$.

By the same process we may project the line of potential

FIG. 37.

in a circuit when there are branches at several places, as, for instance, in a line having faults at certain distances. Suppose thus in Fig. 36 C B to be battery resistance, and B A the line three miles long, having at the battery pole, B, and at the first and second mile a leakage fault having a resistance equal to two miles of line. Then first we must find the joint resistance of the last fault towards the earth end and the last mile. This, it will be seen, is done by erecting a perpendicular at F, then at B (two miles from F) and cutting off B O equal to two miles. Joining O A, we cut the perpendicular erected at F, at R, and making F I = F R, we get C I as the total resistance of the circuit if there were no other faults.

Digitized by Google

Proceeding in the same way with the fault at G, we get C J as the total resistance if the fault at B did not exist. Now, proceeding in the same way at B, we get C K as the final total resistance of the circuit. Joining E K gives B L as the potential at the battery pole. Joining L J gives G M as the potential at G, and joining M I gives F N as the potential at F. The line of potential from the battery pole L to the end at earth at A is thus given by the lines L M N A, and the current issuing from the battery is $\frac{C E}{C K}$, and the current issuing at the end to earth is $\frac{F N}{F A}$. Had there been no faults in the line the potential at the battery pole would have been B Y, and the current throughout the circuit would have been $\frac{C E}{C A}$.

It is easy to see that in a line which leaks uniformly throughout, as, for instance, in a subterranean line, insulated with some uniformly bad material, the line of potential will become a curve, as shown in Fig. 37.

THE INDUCTIVE AND CONDUCTIVE CIRCUITS.

BY JOHN T. SPRAGUE.

It is generally considered that static electricity and dynamic electricity require distinct treatment. The result is that few people acquire clear conceptions as to both branches, and the formulæ and laws of the one are apt to prove an encumbrance when studying the other. The real distinction between the two is, however, nearly unknown, and not pointed out in any of the books. That distinction is that there is no such thing as a *quantity of static electricity*. It is quite true that we have two definitions of such a quantity, but those definitions themselves disprove its existence when studied.

The coulomb appears to be a unit of quantity, and it really is so as to dynamic electricity. The microfarad appears to be a receiver capable of comfortably holding a quantity of electricity like a pint bottle would a quantity of air, and that in ratio of the pressures put upon it.

The coulomb is, however, a quantity of electric *action*, not necessarily a *quantity of electricity*, even of dynamic electricity, because its truth and utility are equal, whether we consider electricity as an entity, a fluid, or as merely a function of molecular or etherial motions and changes. Its value is fully definable as a material, actual quantity, because it releases a definite weight of hydrogen or other substance. This gives it a quantitative material value. A micro coulomb is one-millionth, and we can bottle this up in a microfarad and take it out again. Is that quite sure? Is it *electricity* we have put into our bottle?

What is the microfarad? The only essential part of it is a *dielectric*. The coatings only serve as the neck of the bottle, a pathway—electrodes. What, then, is a dielectric? It is a substance in which a certain state of *stress* can be produced, developing a *field of force*; that field of force is of such a nature that it is produced by what we call electricity, and will give us back the energy stored up in the stress as electricity again. Then it may be energy stored under particular conditions, not electricity, just as in secondary batteries we can store energy in the form of chemical affinity ready to reproduce electricity.

The other unit of electro-static quantity is that quantity which, placed at unit distance, repels an equal similar quantity with unit force. But the very definition tells us that this is a quantity of a force; it is simply the reaction of the "field of force" existing between the two electrodes.

Returning to our bottle of air, we find in it two things, a "quantity," the air itself—a "pressure" exerted by the air. Are not these the two things we find in electricity—a something definable as a "quantity" in dynamic electricity, which something exerts a "static pressure," related to the energy charged upon the "field of force" generated in that air? In this case, however, the air itself plays the double part; in electricity, whether there be a quantity of it having existence or not, it needs another substance, the dielectric, to store the energy, which, however, it may be said, corresponds to the material of the containing bottle.

The distinction drawn does not depend on the analogy, for this always fails at some point. The point itself is that the phenomena of static electricity, are related, not to quantities of electricity, but to energy operating in a field of force; whenever "quantity" comes into play, as in discharge, we are no longer dealing with static, but with dynamic electricity. To make this clear it is necessary to consider some of the actions which occur.

According to the mathematical theory of electricity, current, &c., discharge, &c., are due simply to *difference of potential*, the actual position of the two points on what we may call the "scale of potential" having no influence. This is, of course, analogous to currents generated in a column of water, which may be regarded as a "scale of potential;" such a current issues from any point in the column as is due to the head of water above that point, however high up in the scale it may be itself.

The same effect will arise between two points in an electric circuit, whether those points are at + 15 and + 5 potential as regards zero, and though both of them have free + charges, as would occur between two points at + 5 and — 5, with equal free + and — charges. The facts are, of course, true, and and for some of the purposes of calculation, the theory has its advantages. But the theory is not true as a fact of nature. The water analogy itself disproves it; the column of water below the point at which current passes is inert, *it is not in the circuit*. The same is the case with the electric circuit. It is true that we can have two Leyden jars charged to such differences, with their external coatings connected together, as will represent the scale of potential, the external coatings being the + and —. But then we may connect the junction of the external coatings to the theoretical zero of potential, the earth, and no current will pass. The analogy to the opening in the column of water fails. But why? Simply because we have two distinct inductive circuits. Each jar is complete in itself just as a battery cell is. We can discharge the jars singly just as we can take current singly from two cells joined in series, or we can discharge them in series with the effect due to the sum of the potentials, just as we can use the cells.

In fact each jar, *i.e.*, each inductive circuit, has its own scale of potential, of which the — is at zero. The theoretical, or earth zero, is a mere artificial invention for purposes of calculation; it is precisely the same with the column of water. The total height of the column has no actual relation to the result, and the zero is not the earth level (in fact, if anywhere it would be at the earth's centre); but for each current the real zero is the point at which it issues.

To meet the fact that no discharge will occur at the common junction to "earth," although that junction is at + potential, the other artificial doctrine of *bound* electricity is invented. The free charge on the inner coatings dissimulates an equal quantity on the corresponding outer coating; but what is the use of this complication when the case is absolutely analogous to that of the two galvanic cells? As long as the cells are open, they are under identical conditions with the charged jars; in both there is a break of connection—an inductive circuit between the poles which the force cannot break down. Under these circumstances we can insulate the jars, either connected or separate, and we can give them a *free charge*. But what is this but adding a third inductive circuit? We can even charge the external coatings + or —, but in so doing we simply make the outside surfaces the one coating to the air of the room to which the other coating is the surrounding surface. We can even put opposite free charges on the two jars in the same manner, and we can make these charges either the same or the opposite of the charges which their inner surfaces bear as regards the inner coatings.

All this becomes perfectly clear when we examine each separate inductive circuit as we should the circuits of currents, which every one knows may be absolutely distinct though they all unite at a common point, or even traverse some part of a common conductor.

Digitized by Google

We may now contrast and compare the two orders of electric circuits.

The *conductive circuit* consists of matter which allows electrical action to take place in the form of current, or we may say it permits electricity to pass. It does so in quantities related to the electromotive force, to the conducting capacity of the material substance, and in producing current the electricity expends energy.

The *inductive circuit* consists of matter which does not transmit electricity, but admits of the formation of a field of force manifested as *charge* at its opposite sides. Such "charge" is proportional to the potential, to the inductive capacity of the material called the dielectric, and in producing charge the electricity expends energy.

It will be better now to present the relations in parallel columns:—

Static.	ELECTRICITY.	*Dynamic.*
Energy *potential*; stored in a field of force, as stress in a dielectric	means	Energy *kinetic*; acting in a conducting path along molecular chains.
Inductive.	CAPACITY.	*Conductive.*
Area of dielectric. Spec. ind. capacity of dielectric.	varies as	area of conductor. specific conductivity of material.
Thickness.	inversely as	length.
Inductive.	RESISTANCE.	*Conductive.*
Reciprocal of conductive capacity.	is the	reciprocal of conducting capacity.
CHARGE.		CURRENT.
Potential in Volts.	is as	electromotive force in volts.
Resistance.	inversely as	resistance.
Inversely as the several resistances.	divides among several circuits	inversely as the several resistances.
Lines of forces under stress.	is related to and dependent on	lines of equivalent molecules forming chains.
	ENERGY, OR WORK.	
Square of charge in unit or equal resistance.	is as	square of current in unit or equal resistance.

FORMULÆ.

Charge $\frac{E}{R} = Q$	Current $\frac{E}{R} = C$
Potential $Q \times R = E$	Electromotive force $C \times R = E$
Resistance $\frac{E}{C} = R$	Resistance $\frac{E}{C} = R$.

As to the capacity, the specific inductive capacity is measured in its own terms, by the charge received under unit potential by a unit dimension, as, for instance, a square foot of 1 mil. in thickness of the material. Specific conducting power is usually and most conveniently measured as a resistance of a unit dimension, such as a wire 1 foot long and 1 circular mil. in area. Resistance and capacity being reciprocals of each other it is indifferent under which term it is measured.

The influence of thickness of dielectric is taken here under its simplest form, as a plate whose area vastly exceeds its thickness, which is practically in the form of concentric spheres of very large radius. This is correct, not only because it is simple, but because the comparison is really to be made between the areas which would transmit a unit of current or take up the same unit as charge, and this latter area is many million fold in the dielectric what it is in the conductor.

A TELEPHONE NUISANCE.—"Inspector" writes from Columbus, Ohio: "I have made a discovery which may prove of great value to telephone exchanges throughout the country. Though the experiment will require a considerable outlay, it may prove a saving of time to inspectors and of patience to subscribers which will compensate for the expenditure (for I have also discovered that a subscriber loses his temper in case of trouble with his telephone). One day last week a line was reported open, and on investigation the magneto-bell box was found to be literally packed with cockroaches. The switch had crushed several of them, thus causing the trouble. My suggestion is that the construction men and inspectors be provided with boxes of insect powder and instructions to give every instrument a thorough dosing when it is put up, and every time it is inspected."—*Operator.*

THE SOCIETY OF TELEGRAPH ENGINEERS AND OF ELECTRICIANS' ANNUAL MEETING.

The annual meeting of this society was held at the Institute of Civil Engineers on 14th inst, Lieut.-Colonel C. E. WEBBER, R.E., C.B., president, in the chair. After the transaction of some formal business, the report of the council was read by the secretary. The number of new members and associates had increased during the year by about one hundred; and the funds of the society were in a satisfactory condition, it being stated, for one thing, that life compositions alone, amounting to £741, had now been invested in Government or other securities. Some steps had been taken to place the society on a footing so that it could be registered under the Joint Stock Companies' Act, and it was hoped that correspondence on the subject would be so far advanced very shortly as to enable a general meeting to be called to authorise what was being proposed. The report also recapitulated the various papers read before the society during the year, and the leading events in which the members had taken part. The exhibitions at Paris, at the Crystal Palace, and at Munich, and the visit of the society to Chatham, at the invitation of the Royal Engineers, were specially mentioned; as also some brief reference to the forthcoming exhibitions at the Crystal Palace and the Aquarium. The recent conference at Paris for the determination of electrical units would not complete its report till October next year, to which date its meeting had been adjourned. There was reason to believe that the rules drawn up by the council of the society in conjunction with representatives of the fire insurance societies for the laying down and maintenance of electric lighting wires with special regard to the risks of fire had proved acceptable, as they were being very generally adopted. Those rules were now printed in a separate form as well as in the society's *Journal*. The fund provided by Mr. Fabie, and by the surplus accruing from the Paris Exhibition guarantee, had been invested so as to enable the society to offer prizes for original papers each year; and this it was hoped would prove a stimulus to young members to put their ideas or inventions into shape on paper, and bring them before the society.

The librarian's third annual report was also read. During the year additions to the library to the extent of 245 volumes had been made, chiefly by presentation. A considerable increase had taken place in the number of visitors, showing that the advantages of a library of this kind were meeting with growing appreciation. Although theirs was an electrical library, it was desirable that works—standard works, at all events—on physical science generally should be added to it; and the librarian hoped that the liberality already shown in respect to purely electrical works might extend itself also to works of the kind just mentioned.

The report being adopted, a vote of thanks was proposed to the Institute of Civil Engineers by Mr. E. GRAVES, the hon. treasurer, who in felicitous and graceful terms pointed out how deeply the society were indebted to the liberality of the Council of the Civil Engineers, in whose beautiful and commodious theatre it was their privilege to meet.

This vote was duly seconded and carried by acclamation, as was also a similar vote of thanks, proposed by Mr. Latimer Clark, to the foreign secretaries.

Mr. THOS. J. LARKIN'S paper on "The Application and Extension of Telephonic Communication in Japan" was then read. The chief novelty of Mr. Larkin's paper was in the fact of the Morse instrument in Japan having been largely superseded by the telephone. This at all events appeared to be the case on certain railways, and for the local purposes of police in the chief cities. The telephone had some obvious advantages over ordinary signalling instruments in that it required no skilled manipulators, and was immensely superior to mere bell signals on railway systems in the fulness and completeness of its means of communication between the signalmen. The circumstances of the capital of the country rendered communication of this kind most desirable. The houses being of wood, and extending over a wide area, the outbreak of fire was a thing to be notified as quickly as possible, as also the action of armed robbers, and emeutes, which were of by no means infrequent occurrence, and called for speedy concentration of troops.

In the course of the evening the result of the balloting for the officers of the society for the forthcoming year was announced by the president, the gentlemen nominated by the council all being elected. Mr. Willoughby-Smith was the new president; Sir Charles Bright one of the vice-presidents; Professor Ayrton, Mr. T. Russell Crampton, and Dr. J. H. Hopkinson, the three new members of the council; and Lieutenant A. H. Bagnold, R.E., Mr. Shelford Bidwell, and Mr. J. C. Lamb, the three new associate members of the council.

The next meeting of the society is fixed for January 18, 1883.

THE ELECTRIC LIGHT AT THE NEW LAW COURTS.

Instead of illustrating the switchboard used at Berechurch Hall, as we had originally intended, we give herewith a description and illustrations of the larger ones that have been employed by Messrs. R. E. Crompton and Co. at the Law Courts.

The current from the six dynamos, of which, however, only three were placed on the opening day, is collected in the switchboard shown in Fig. 1, and is led by main cables, shown by thick black lines on the right of the board overhead, and across an at present unoccupied space into the

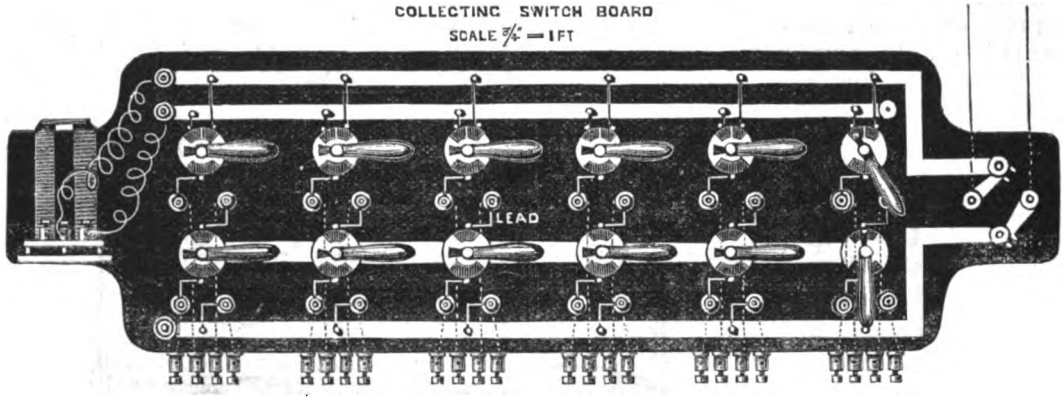

Fig. 1.

main building of the Law Courts, where they are brought across the crypt into a little room which contains the dividing switchboard, shown in Fig. 2. The length of cable between collecting and dividing switchboards is 220ft., or 440ft. for outgoing and returning current.

As regards the collecting switchboard it will not be necessary to repeat the description given in our article on the light at Berechurch Hall. Readers will understand the arrangement from the drawing, bearing in mind that, in each group of four terminals seen at the lower edge of the board, the two inner ones receive the leads from the brushes, and the two outer ones those from the terminals of exciting coils or the field magnets.

It may at first sight seem that by thus bringing every lead to the switchboard an unnecessary amount of cable is used, as the object could also have been obtained by simply joining all the positive brushes by a stout wire laid direct on the dynamo platform; but this plan, although not requiring such long leads, would require contact breakers between each positive brush and the joining wire, which would be a source of danger. It will easily be seen that were any contact breakers left open by mistake, and the dynamo then switched into circuit, there would be a reversal of polarity and burning up of the machine. In the form of switchboard designed by Messrs. Crompton such an accident is absolutely impossible.

To the left of the board is placed a Siemens dynamometer, by which the current given off by any single machine, or by two or more machines collectively can be measured. On the right of the switchboard is placed an arrangement for reversing the current. This is not an ordinary reversing switch, as, with the heavy current of 300 to 400 amperes, such a switch would heat too much. It consists of two pivoted contact pieces, which are pressed on to the terminals by large mill-headed screws. Thus a very close contact is ensured and heating avoided.

The current enters the dividing switchboard at *a*, and leaves it at *b*. The arrangement of the different connections will be clear from the drawing. An ammeter is placed as shown, and so connected that the current going to any part of the building can be made to pass through it by simply turning the handle of the corresponding switch. Our illustration shows, for instance, the switch of Court 14, so placed

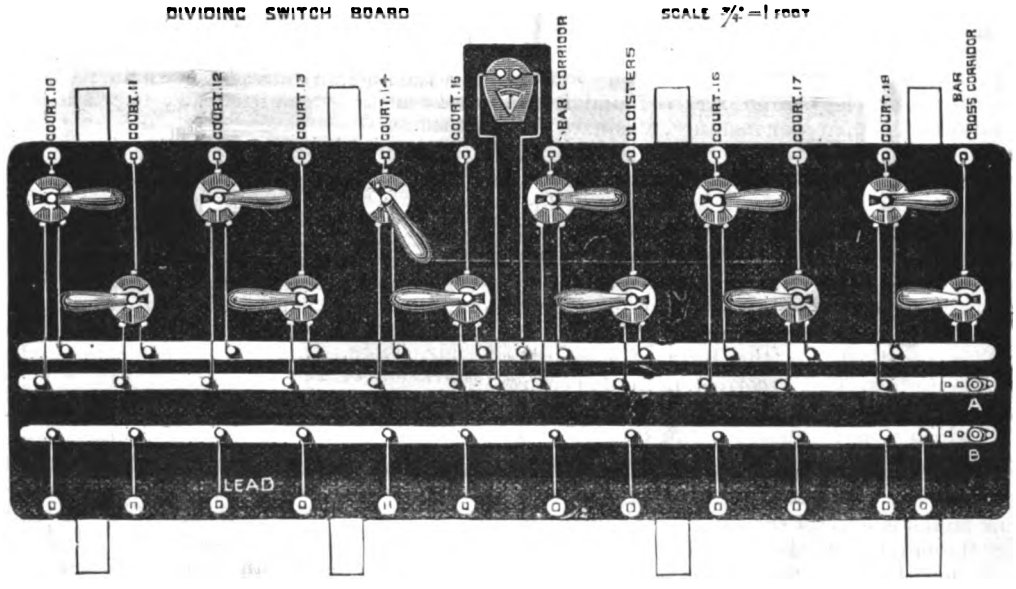

Fig. 2.

that the current flowing to that court is being measured. The leads are carried in grooved planks, and are so arranged that in no place does one lead lay across another.

Lead cuts out are provided in switchboards as shown.

A special arrangement deserves mention by which the driver in the engine house can see at any time to what degree of brightness the lamps in the courts and corridors are being excited. It will easily be understood that, although the dynamos are self-regulating, and, therefore, keep up a constant difference of potential on the collecting switchboard, yet the difference of potential on the dividing switchboard must be less by the electromotive force required to

Digitized by Google

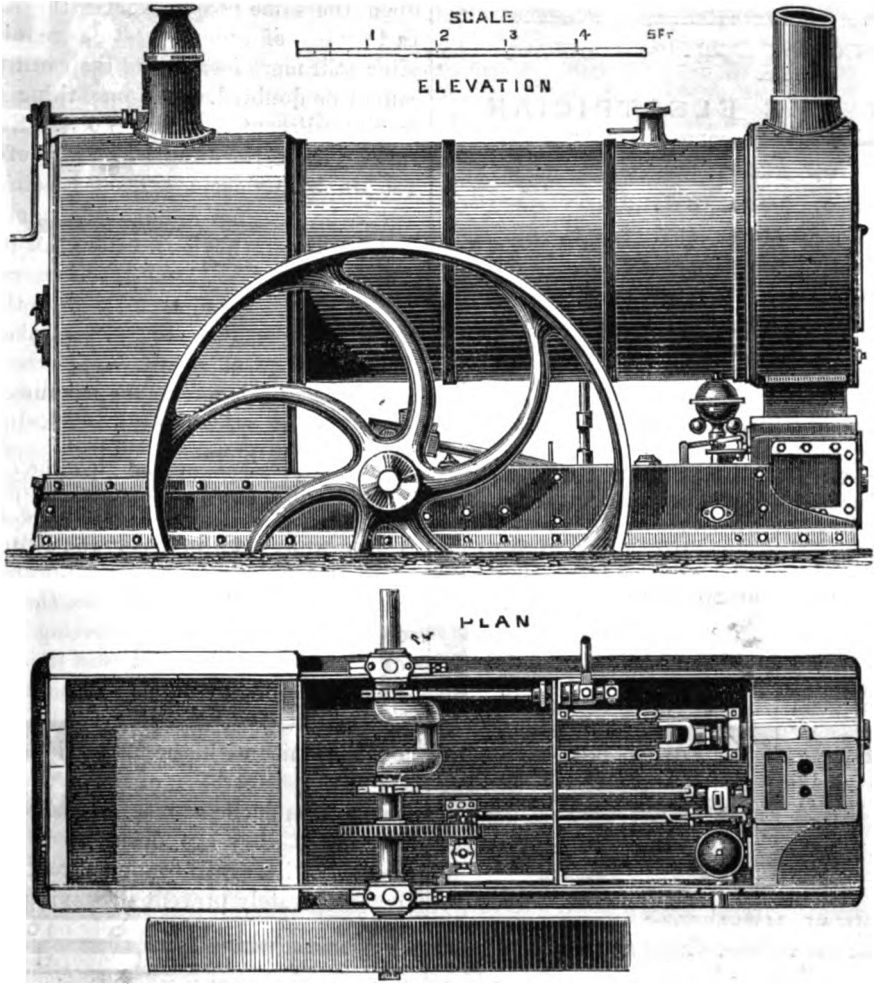
overcome the resistance of main leads. This loss of electromotive force again is not constant, but depends upon the current flowing—that is to say, upon the number of lamps which happen to be burning at any given time. In all there will be 12 circuits fed from the dividing switchboard, and equal brightness of all the lamps is obtained by so proportioning the resistance of branch leads that exactly the same E.M.F. is lost in each of the 12 branch circuits. Thus as long as the E.M.F. at the dividing switchboard is kept up to its proper value all the lamps in the building will give the right amount of light. But that this should be the case the electromotive force at the collecting switchboard must be slightly varied in accordance with the amount of current sent out. This is obtained by a slight variation in speed.

In order that the driver may know what speed to run, four Swan lamps are placed in the engine house, and are fed not direct from the dynamos but from a pair of No. 16 insulated wires brought back to the engine house from the dividing switchboard in the crypt. The loss of E.M.F. in this No. 16 wire feeding four lamps is exactly the same as that in each branch circuit in the building feeding from 22 to 30 lamps, and, therefore, the four lamps in the engine house will, at all times, have the same degree of brilliancy as those in the courts. They serve, therefore, as a guide to the driver, by which to regulate the speed of the engine.

The lamps in the engine house fulfil the same office, in fact, in connection with the electric light as the gas burner does at the gasworks—the luminosity of the lamp in the one case giving the engine driver an indication of the speed required, the luminosity of the gas indicating the pressure required.

DAVEY, PAXMAN, AND CO.'S SEMI-FIXED ENGINE.

We herewith illustrate a semi-fixed engine built by Messrs. Davey, Paxman, and Co., of Colchester, and used as the motor for driving the dynamos at Berechurch Hall. This firm has been giving some attention to engines for electric purposes, and modifications in the designs for the ordinary engines have been made for the special requirements. Our illustration explains itself, but these engines are made with either double or single cylinders. The working parts are under the boiler, in order to obtain steadiness. The bearings are extra long and of gun metal. The crank shaft is of steel, and takes the flywheel on either side. The piston, valve rods, &c., are of steel, and have the working parts case-hardened. The boiler is of the ordinary multi-tubular type, well made of the best materials, and having about 20 square feet of heating surface per horse-power. The fire-box is of mild steel. The engine is fitted with sensitive governors. Engines of this type have been carefully tested and found fairly economical. We believe Messrs. Crompton and Co. intend to use two similar engines at an installation now in progress. It is a sign of progress that our engine builders should devote their attention to the designing and construction of a special class of engines for electric light purposes. Like some other makers, Messrs. Davey, Paxman, and Co. have issued a special catalogue describing and illustrating their construction of engines for driving electric light machinery, and, no doubt, their well-known excellency of construction will direct the attention of engineers to engines of their build.



Davey, Paxman, and Co.'s Semi-Fixed Engine.

BRUSH MIDLAND ELECTRIC LIGHT COMPANY.—The petition which was recently presented for the winding up of this company was withdrawn last week, the company paying costs.

NEW CABLE.—News from the colony of South Australia says that a cable has been successfully laid between Yorke's Peninsula and Ironbridge Lighthouse.

ANNUAL MEETINGS.

The aptitude of the English people for self-government has been often commented upon by foreign critics; and our business ways of procedure, when common objects are aimed at by means of friendly combination, are admired even by nations most inclined to disparage us. If the net result is seldom brilliant, it is always substantial. The solid advantages we derive from patient, united, and disciplined effort more than counterbalance the absence of those startling, but less durable achievements, which impatient, premature, or ill-regulated genius may boast of elsewhere. If we do not advance by leaps and bounds, we cover quite as much ground, and do not tire so soon. One chief cause of this is, as foreign observers have noticed, our attachment to forms of procedure. However superfluous they may seem to be in given circumstances, we gravely go through with them as though they were a religious duty; and however ridiculous or vexatious they may appear to be at times, we submit to them without a smile and with hardly a murmur. All this because we have learnt by long experience that forms help us to realities, and that to conduct a meeting according to traditional usage, with none of the formalities omitted, when there is no occasion for them, is most excellent training for the serious occasions on which they really are wanted.

One of the traditional usages to which we are much attached is the annual meeting. The utility of the annual meeting need not be dwelt upon; indeed, it were better not to dwell upon it, for it is one of those things more beautiful as well as more easy to imagine than to describe. One hears a great deal that we knew before, and much beside that we could just as well have waited for a little longer; we are told with more or less candour the exact condition of affairs, which condition is not in the least affected by being talked about; the officers have all done their duty and are dutifully thanked; then the officers for the ensuing year are duly chosen, the choice, by strange coincidence, always falling upon the same people, or else the same people's nominees. In the case of annual meetings required by statute, they are often still more formal, but their utility, or contingent utility, cannot be doubted. For one thing they afford outlets for possible discontent and protest. Except for contingencies such as these, the annual meetings of societies like that of the Telegraph Engineers and of Electricians would hardly be worth the holding. We mean this, of course, from the immediate and more obvious utilitarian point of view. Only on the broader principles of tradition can any good be seen in asking people to ballot for officers the election of whom is made sure by the very steps taken to give the ballot an appearance of a popular election, whilst in reality the whole business is a foregone conclusion. One of the last trying ordeals of a retiring president is to keep his countenance while he announces that certain gentlemen whose familiar names he deciphers with apparent difficulty have been elected on the council by the votes of the members of the society. It may be well to keep up appearances, and it will be seen we are strongly in favour of appearances; but while we are about it we might as well do the thing thoroughly. The society we are just now referring to has, for two or three years past, delayed sending out the balloting papers until the contingency of any opposition on the part of the members was entirely past. This is a needless provocation, which does not harmonise with the national prejudice in favour of law and order. Members of learned societies are, it may be assumed, as docile as members of vestries and corporations, but unless they are different in other respects they will some day kick against going through a formality which they are deliberately prevented making real. Continued reverence for forms depends entirely on our reverence for the things they signify. The ballot papers lately received by members of the Society of Telegraph Engineers and of Electricians signified nothing, and could not by any possibility signify anything.

To the elections themselves, however, hardly any exception has been taken. One really good element in the annual meeting is when it brings a change of officers. That society must be very humdrum indeed if the introduction of fresh officers, new blood as it is called, does not infuse new life into its affairs. However slow or badly managed it may be, there is hope in the changes impending, and its members learn to be patient. No society can afford long to dispense with the revivification which the annual elections effect in its composition; and the society with whom we are more particularly concerned is fortunate in having a constitution which makes these annual changes compulsory. A fresh president, one new vice-president, and several new members on the council look almost revolutionary, and we quite appreciate the difficulty sometimes experienced in getting the annual vacancies adequately filled. But the principle is good, and

Digitized by Google

we believe it will work well so long as the general body of members do not suspect that they have no voice in the matter. We have only heard one complaint as to nominees of the council this year, and this was because of the paucity of representatives of electric lighting enterprise. Time, however, will mend this defect, if it is a defect, the remedy being, probably, forthcoming at no more distant date than the next annual meeting. The anomalous position for some time past of one *de facto*, though not *ex officio*, member of the council has been this year set right, affording an illustration of what we mean by the value of patience as taught by our annual meetings.

For so young a society its position and standing in public estimation are almost unprecedented. From year to year it has gone on rapidly increasing its number of members and adding to its prestige. One cannot help regretting that some valuable contributions to electrical science find their way to a still younger society devoted to purely physical subjects; but this, though unavoidable at present, may be rectified in time if electrical science is allowed to maintain its due prominence in the elder society, now that its title is enlarged so as to embrace the physical as well as the engineering aspects of electricity.

In two other respects the society has been especially privileged. Its place of meeting is not only handsome and commodious, but, thanks to the liberality of the Council of Civil Engineers, it costs the society absolutely nothing. But for this circumstance its funds would not be in the flourishing condition they are now reported to be. A spacious, luxuriously-appointed meeting-house is an attraction of itself, and, as the hon. treasurer in tendering thanks for the use of it remarked, is a practical help to good meetings and good debates. To munificence of a more personal kind the society owes its library, a quite unique collection to begin with, and one which, so contagious is liberality, promises to become one of the best and completest technical libraries in the kingdom. In all points, therefore, the Society of Telegraph Engineers and of Electricians is to be congratulated on the report it was able to present at its eleventh annual meeting. The fact is gratifying also to our readers, who are interested more or less in the welfare of this representative society. To one and all alike we wish that a merry Christmas may reward them for the toils and anxieties of the year.

A CONTRIBUTION FROM A LADY SUBSCRIBER.

There was a kindly field Magnet,
Who loved with all his might
A wild revolving Armature,
With commutator bright.

He tried to woo his fair sweetheart
By messengers of love,
By lines of force sent right and left,
Below and from above.

Love's labour lost! Proud Armature
Threw Magnet in despair,
With reckless whirl she thwarted him
Till he no more could bear.

His field got shifted more and more,
In vain he cried, "Hold on!"
It was too late, her coils were burnt,
Fair Armature was gone!

Now, maidens, take this tale to heart,
And never slight your swains;
Lest hurting them you hurt yourselves—
As Dr. Lodge explains.

CORRESPONDENCE.

THE ACTION OF MICROPHONES.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In your last issue appear nearly three columns under the above heading in the form of a letter from Mr. R. D. Smillie, electrician, Glasgow. I do not presume to doubt that Mr. Smillie is an electrician—he, himself, has said it—but I will venture to assert that he knows next to nothing about the subject he has taken in hand. His experience of the Blake transmitter must either have been extremely limited or has borne strange fruit. He begins by saying that he has discovered that Professor Blyth and "the distinguished physicists" who agree with that "learned professor" (the quoted words are your correspondent's) are entirely mistaken in their assertion that the resistance of hard carbon does not diminish under pressure. And then he proceeds to give full details of the experiments upon which he founds his conclusion; in other words, he proceeds, with much pain and circumlocution, to prove himself in the wrong, and Professor Blyth in the right! The peculiar action of the microphone, as explained by Professor Hughes, is due to the varying pressure, and, consequently, varying electrical resistance, caused to exist between two conductors, lying in slight or loose contact, by agitation in the medium surrounding them. Professor Blyth has amplified this explanation, not contradicted it. He has proved that one conductor may jump slightly clear of the other; but, inasmuch as a current is passing between them at the time, electrical communication is not broken, owing to the formation of a minute arc, or a number of minute arcs, simultaneously with the momentary interruption of the contact. He illustrates this fact by means of an experiment—that of a continuous arc due to 20 Grove cells—which has earned the ridicule of Mr. Smillie, but which is not the less instructive on that account. What does your correspondent do to prove his assertion that microphonic action is due to compression of the carbon and not to variation in the resistance of the contacts? He takes a microphone, the conductors of which are pressed together with a force of 45 grains. He blows upon it with bellows, and tickles it with a bristle plucked from a broom, thereby causing one of the conductors to press against the other with a force greater than 45 grains. What happens? Precisely what Professors Hughes and Blyth tell us—*i.e.*, the resistance of the contact between the conductors is diminished. He ceases to blow, and to tickle, and lo! the contact re-acquires the resistance proper to a pressure of 45 grains. Is there in all Mr. Smillie's three columns one iota of proof that the carbon was compressed? Not one. Let Mr. Smillie remove the carbon button from his Blake transmitter, and replace it by a metallic button. Let him bring his platinum stud against the new button gently, so that the current from a No. 2 Leclanché will just pass, and no more. Then let him blow upon and tickle his diaphragm as before, and inform you, Mr. Editor, whether he thinks the diminished resistance which he will observe *is still due to the compression of the carbon button.*

I do not know whether the remainder of the letter is worth reviewing; but it is amusing to note with what innocence Mr. Smillie publishes his four "deductions" as though they had not—the first, of course, excepted—been perfectly well known to every telephonist since 1878; and how completely he must have misunderstood Professor Blyth's paper when, in the last paragraph, he attributes to him an intermittent contact—*i.e.*, make-and-break-theory.—Yours, &c.,

London, Dec. 18, 1882. LOOSE CONTACT.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: If Mr. R. D. Smillie is correct in his deductions from his experiments with bellows, bristles, and breath, what is there to prevent us from doing away with the platinum stud P altogether, and joining R to B in the primary circuit, in the same way that S is connected?

I, for one, see nothing in his experiments that is out of

Digitized by Google

harmony with the theory of loose contact, which is the same as a bad joint in a wire—it increases its resistance. Pressure on the microphone makes the contact closer, hence the greater deflection of the needle, which regains its former position as the pressure becomes less. This pressure on the microphone acts the same as the wire, in having the defective joint improved, *i.e.*, the contact becomes improved, calling forth more energy from the battery, as the needle shows. If there were no make and break taking place, a piece of carbon, to which two binding screws were attached, ought to be sufficient to speak with. As the experiments are not yet complete, may I suggest that he constructs one as stated, to forward with his next batch.—Yours, &c., J. RATHBONE.

COMPOUND MACHINES.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: To use one of those witty Americanisms that, whilst not slang, have all its piquance, your contributor, Mr. Gisbert Kapp, in attributing to Messrs. Crompton and Co. priority in the practical development of dynamos wound on the shunt *and* main circuit principle, is a little "too previous." The first to practically develop this idea was Mr. C. F. Brush, the eminent electrician, who has brought Cleveland, Ohio, into notice as an electrical centre. He wound the main circuit on the same magnets as a shunt circuit, which he terms a "tenzer." But he does this for a special purpose, and that is in electro-plating machines to prevent the back-action of the bath depolarising the electro-magnets, to which the chief generative effect is due. His purpose was not to obtain a constant electromotive force; nor could it have been obtained by his arrangement. In 1878, when I wrote my book on electric lighting—now far behind the times—I gave mention in a chief place to the Brush machine, then unknown here, because I considered it to be the machine of the immediate future, as it became, and I then pointed out that this principle of double winding was applicable to the purposes of light and power. Later on I built a machine wound on this principle, and followed it up with others, not because the first was a success, but because it was a failure, the cause of which needed working out, as it was not, as a failure, at all in accord with (subsequently successful) theory. In these failures I wound my shunt-magnet circuit on the *same magnet cores* as my main magnet circuit. The result was a flickering unsteady light, and an unaccountable breaking down of insulation in the shunt circuit coils. The reason was hard (for me) to find; but being found it is very easy to give. Wound thus, the main-circuit formed a primary, and the shunt-circuit the secondary of a powerful induction coil, the potential of which, it is easy to see, became in this secondary enormous. For instance, suppose, as was the case, an arc lamp burning in the main-circuit; sudden extinction, by separation or breaking of the carbons, developed powerful secondary currents in the shunt-magnet circuit, which not only affected the working of the machine, but pierced the insulation of the wire, and besides were dangerous. Indeed, on a parallel wound wire long and dangerous arcs could be obtained by severance of the main circuit. This palpable result of experience should be, with the dates of my patents, some evidence to show that the Messrs. Crompton were *not* the first to work out this idea into practice. I cannot spare Mr. Kapp this contradiction, because, in quoting Professor Bosanquet's letter, he would have found reference to the statement, from the manager of the company controlling my patents, to the contrary of what he asserts. So far I consider his neglect wilful.

With your permission I will state how, after much expensive experiment and study, I got free from this defect I have mentioned. The expedient I adopted is to wind the shunt magnet circuit and main magnet circuit on *separate* magnet cores; and since then I have not had the least trouble. It is easy, by a simple alteration of connection, to keep either the electromotive force or the quantity of current constant. The method has been applied to the Gramme machine with good results, but among the best results were those obtained with a machine, so altered, of Mr. James Wood's invention, and made by the Fuller Company—a machine that of itself deserves to be much better known here both as a very light-weight and effective machine.

This method of winding is described in my American patent, No. 242,644, applied for March, 1881—that is, in the spring of the year *previous* to that mentioned by Mr. Kapp as that of his work under Messrs. Crompton's direction; and it also has been patented in all European countries.

Whilst I deprecate the assumption made by Mr. Kapp I should be open to accusation of great oversight if I were not to acknowledge the very candid reference to my name made by Professor Bosanquet. So definite and noble recognition of another's priority in one's labours is unusual, unfortunately, at least in my experience. I should feel corroboration on my part uncalled for, as to the practical reliability of Mr. Bosanquet's investigation, were it not that Mr. Kapp attacks it.

There are obviously three heads under which the subject may be considered (*a*) That in which the most of the excitation is done by the shunt-circuit, and only a certain proportion by the main, (*b*) in which the circuits play an equal part, (*c*) in which the shunt-circuit plays only an initial part.

There are uses for each of these arrangements. Mr. Bosanquet's remarks apply to (*a*) as far as the limit of (*b*), so far besides as relating to the maintenance of a constant E.M.F.

But, beyond these three heads, a much larger field for inquiry is opened up by the use of separate cores for the main and shunt circuits—a field that I have been exploring for the last three years with all the aid of hard mathematical study, as well as with large assistance from those essential "exhaustive and careful experiments" Mr. Kapp arrogates to himself and his friends. For instance, we may make all the S poles of our machine come within the magnetising influence of the shunt circuit, and all the N poles within that of the main circuit, or we may differently apportion them. It is possible and easy thus to make a machine that shall give either constant E.M.F. or C, with varying R, within certain limits, *and above or below those limits cease to give any current at all*—an arrangement peculiarly safe where enormous currents are dealt with. And we can make the limits of constancy so narrow as the machine becomes almost galvanometric.

Permit me to add that these results have been obtained practically only with expenditure of money greater than a single individual would be likely to undertake, and that the proprietary vests, as regards the patents for Europe, in the Higgs Electric Light and Power Company; that this company, through its *concessionaires*, are building, and have built, several machines, but have purposely and stringently avoided advertisement for business reasons; and I think the chief of this ground is covered by the patents of Brush and myself. As business men who have laudably assisted in developing new ideas, I asume my friends will *not* make a present to the world of the scientific facts I have discovered for them during my investigation. Hence my personal reticence on the subject in technical journalism.—Yours, &c.,

Paris, Dec. 18, 1882. PAGET HIGGS.

SECONDARY BATTERIES.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I was present last night at a lecture given by Mr. Reckenzaun, the well-known electrician to the Electrical Power Storage Company, at the Limehouse Town Hall, and was pleased to see a large and attentive audience listening to his explanations, and taking great interest in his excellent and instructive experiments.

The principal feature of the evening was the experiments made with *secondary batteries*, and I have no doubt that a few words on the subject will interest your readers.

These secondary batteries were of the Sellon and Volckmar type, and, as far as I can learn, were charged at Millwall, and carted to Limehouse to be used there, before the audience,

Digitized by Google

for driving a lathe, sewing machine, for lighting an arc and several incandescent lamps.

This is, I believe, the first time these secondary batteries have been shown in public since their exhibition at the Crystal Palace, and there cannot be much doubt that they are the only ones that have left the stage of laboratory experiments for the sphere of useful and important commercial commodities.

A very noticeable and important feature also was the lighting of the Pilsen arc lamp. I believe that this is the first time that an arc lamp has been successfully lit up by accumulators, and I think that if Mr. Reckenzaun would kindly favour the public with some details of the practical construction, and his no doubt great experience of the working of the Sellon and Volckmar battery, and also of his arrangements for lighting arc lamps by their means, it will be of great public interest.—Yours, &c.,

29, Aldermanbury, E.C., BLYTHE UNWIN.
December 14, 1882.

A TELEGRAPH LINE WITHOUT INSULATORS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Pressure of business has prevented me replying to "M. Practical" sooner, or I should have been pleased to do so, and should thus have saved your (2) correspondents their intense anxiety on my behalf.

I am surprised to find that a telegraph engineer with such a knowledge and experience as "M. Practical" would appear to possess should have discovered for the first time from my letter that it was possible to work a telegraph line nearly 200 miles long without insulators, especially in Japan, where, as I stated, the climate is so favourable to insulation. They were worked with Siemens's best inkwriters, which a man of "M. Practical's" experience should know are also usually supplied with very sensitive relays, our case being no exception to the rule, each relay being most carefully made and wound to 300 ohms resistance.

How a telegraph engineer with the extensive knowledge and experience claimed by "M. Practical" can have learned also for the first time of the existence of a water battery is curious, but for "M. Practical's" information, who is evidently unaware of the fact, I may say that the water battery was extensively used some fifteen or sixteen years ago in cable experiments. A quart-sized cell made up of water alone gave an E.M.F. of ·936 volts, while the internal resistance was 19 ohms.—Yours, &c., J. O. F.

IS THE MICROPHONIC CONTACT AN "ARC?"

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In Professor Blyth's Experiments on Microphonic Contacts, p. 42, he comes to the conclusion that the action of a transmitter can be analysed as follows:—

"It is a break and make like the Reis, with the addition of material filling up the gaps."

I beg to propound the question whether, electrically speaking, a filled up "gap," and, therefore, an "arc," is indispensable in the action of the transmitter.

Some time ago I proved that if a Blake transmitter was enclosed in an ordinary vacuum its resistance was less by two-tenths of an ohm, and that this two-tenths represented the thin stratum of air between the contact electrodes.

Now, while it is possible with a comparative large electromotive force to produce what is termed an "arc," I cannot believe that the two volts of a Leclanché cell acting upon a resistance of about five ohms of a Blake transmitter can produce this phenomenon.

But, of course, while the sound is acting the stratum of air becomes wider, and its resistance increases enormously; but even then it merely represents so much resistance, and not necessarily an "arc" meaning a discharge of particles.

The very fact that at a loose contact there is a "mechanical gap" between the parts in "so-called" contact, which is filled up with air of two-tenths ohm or more resistance, does not make it an arc any more than if the "gap" was filled up with other matter representing that resistance. The great advantage of air as a contact medium is that it is highly elastic and does not stick to the electrodes as a liquid would by capillary attraction under similar conditions.

Furthermore, the condensation of air upon a carbon surface may well account for why this material is so well adapted to the purpose of a transmitter.

Professor Blyth proves the correctness of the aërial contact idea as always advanced by me, and shows, too, the experiment of transmitting by means of an arc; but that does not prove that an arc is necessary.

I once examined a very hard and highly polished carbon button which had been in constant use in an all carbon loose contact transmitter (with one cell gravity) for ten months, and I could not discover the point of contact, showing that no deterioration had taken place. Yet many million times had this contact vibrated and faithfully transmitted speech. Is it possible that in this case a transfer of carbon particles, an "arc," had occurred?

It is, however, certain there was an air layer continuously changing its resistance between the electrodes.

Now, if two electrodes separated by an air resistance of two-tenths ohm are called in contact, why are they not so when this resistance is 20,000 ohms? and if this is not a contact, where does it commence to be an "arc" unless there is a transmission of particles?—Yours, &c.,

E. BERLINER.

MR. CROMPTON'S APPLICATION OF THE SWINBURNE WINDING.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Though no one will grudge credit to the first maker of compound dynamos in any particular country, I think Mr. Crompton did not introduce the idea into England, and was not the first to try the system, or to use it commercially. Though it is highly improper to talk of one's own doings, I tried the system early in February, having previously independently invented it, and described it to Messrs. Swan and Co., of whose French factory I had charge, my letters fixing the dates. A dynamo having been sent accidentally wound with the wrong size of wire, this system was applied with success, and the dynamo used. I wished to patent a dynamo of which this winding was the chief characteristic, but found that Mr. Brush had used a fine shunt wire as a "teazer," I believe, to prevent reversal of a machine for plating, from which circumstance the invention was credited to that eminent inventor. As the rest of my machine may yet be protected I will hardly be expected to describe it; but it is evident that the change of the ratio of work done in the bobbin of a shunt machine to the work done outside is not alone to be considered. As will probably be dealt with in M. Kapp's second paper, the points of greatest magnetisation are moved when the current in the bobbin is altered; and this current also induces a counter E.M.F. in the wires of the field-magnets. This last phenomenon seems to have been first mentioned only quite recently in England, though I have lately found that M. Joubert wrote of it in 1881, and will, no doubt, again discuss it in his forthcoming work. Having to instal a large Swan works in America, I asked Mr. Brush if he would kindly have compound dynamos wound for me. I have not the figures of these, but think the variation in speed necessary was only 2 or 3 per cent. up or down. The application of this winding to give a uniform E.M.F. at the terminals of the machine, which will probably soon be the regular way of winding dynamos, seems far more important than that for getting a uniform C for lamps in series. To get uniform E.M.F. on work with resisting leads interposed is more troublesome. A machine should not only adapt itself economically to its work, but should compensate for the ordinary irregularities of the driving engine. I have reason to think this can be done automatically with practical accuracy, without shifting the brushes or using any mechanical regulators. My extreme modesty prevents my suggesting, or even remotely hinting that, if I first introduced the sys-

Digitized by Google

tem of double-winding self-exciting machines, it be called the "Swinburne Winding," so I will not.—Yours, &c.,

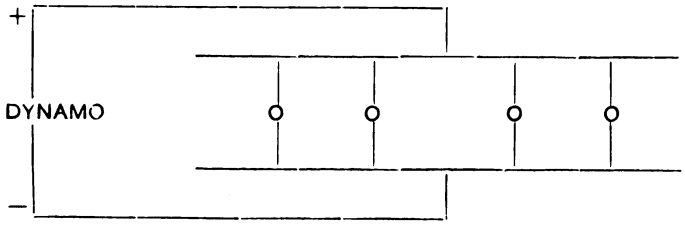
JAS. SWINBURNE.

December 16. Late of Swan I.E.L.Co., U.S.A.

INCANDESCENCE LEADS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I have carefully read Mr. G. Kapp's paper on incandescence leads in the number for December 9th. It occurs to me that a mode of more equally distributing the current



so that there should be less difference in E.M.F. between the lights nearest dynamo and those at the far end of leads would be to arrange matters as in this diagram, instead of beginning to draw off E.M.F. at the nearer end of circuit.—Yours, &c., W. T. F.

[We should be glad if correspondents would remember that our columns are open to scientific discussion, and that personalities should be avoided. We think that some of the letters in this week's number bear on the personal rather than the scientific.—ED. *E.*]

MR. W. T. HENLEY.

Mr. William Thomas Henley, the well-known telegraph engineer and contractor, of North Woolwich, who died on Wednesday, the 13th inst., in his 69th year, was one of the early pioneers of practical telegraphy in this country. Mr. Henley was born at Midhurst in Sussex. After receiving a good education he was brought up to the leather trade, but not liking that business, at 16 he left the country and came up to London to seek his fortune. He began as light porter at a silk mercer's in Cheapside, and afterwards worked in the docks as a labourer for some years. Meanwhile he taught himself the trade of a philosophical instrument maker, and at 24 years of age he started in business as an electrical instrument maker. When Professor Wheatstone brought out his first electric telegraph Mr. Henley was employed to make the apparatus and assist at experiments. When the first Electric Telegraph Company was formed in 1846 Mr. Henley did a large amount of work for them, but having partially executed a large order for the company, which they for some reason cancelled, he went to law with them, and they consequently gave him no more work. He then invented the magnetic telegraph, and in 1852 formed a powerful company, called the British and Irish Magnetic Telegraph Company, to whom he sold his patent for £68,000. Lines were laid by Mr. Henley for this company underground between London and Carlisle and between Dublin and Belfast. The Magnetic Company, of which Mr. Bright (now Sir Charles) was the engineer, became a powerful rival to the Electric Telegraph Company, and Mr. Henley continued to supply the company with his magnetic instruments.

In 1857 Mr. Henley began making submarine cables at Enderby's Wharf, East Greenwich, making in that year 30 miles for the straits between Ceylon and the main line, and nine miles for Egypt, and in 1858 he made 240 miles, at the same works, for Bass Straits, between Tasmania and Australia. In 1859 he built the well-known cable factory at North Woolwich, and in 1860 made the 365 miles for joining the Balearic Islands with Spain. He made several cables of shorter length in 1861, and in 1863 made 1,651 miles of heavy cable to the order of the Indian Government for submergence in the Persian Gulf. The core of this, and indeed of all the others previously, was supplied (in this case to the Government) by the Gutta Percha Company, which soon afterwards, combining with Messrs. Glass and Elliot, formed the Telegraph Construction Company. Thus Henley, having no means of obtaining core, had to make permanent arrangements with the Construction Company. From a very early date at these works he commenced to galvanise wire and other ironware, and soon after set up machinery for drawing wire, and drew all his own wire. Later on still he commenced rolling his own iron, and making also steel wire, and covered copper wire with india rubber. Altogether he manufactured here some 13,000 miles of cable. Besides these works, which covered some 18 acres of ground, and where he at one time employed as many as 2,000 men, he had iron works in Wales and collieries; and at one time he had three ships—"The Africa," "La Plata," and "Caroline," all fitted for telegraph cable laying, and from which ships many cables were laid at Mr. Henley's risk as contractor. For some six years he was making profits of £80,000 a year, but we believe the iron works in Wales were the beginning of misfortunes, and in about 1874 Mr. Henley failed for about £500,000. In 1876 a limited liability company was formed to carry on the work under the title of W. T. Henley and Company (Limited), of which Mr. Henley was managing director, but this eventually was wound up, the bulk of the ground and works becoming the property of the Telegraph Construction Company. This portion was closed, and now remains idle. A portion of the works was formed into the present company in 1880, under the title of W. T. Henley's Telegraph Works Company (Limited), of which company Mr. Henley was a director up to the time of his death. At these works he manufactured his ozokerited india rubber core, which was one of his latest patents of consequence.

He was an exhibitor, and obtained a council medal for electricity and magnetism, at the Exhibition of 1851. He was early in the field as a maker of electric light apparatus, having made machines for the Alliance Company in 1849.

Mr. Henley was altogether one of those extraordinary examples of self-reliant and self-made men. He was eminently inventive and enterprising, and thoroughly practical. He was devotedly fond of his works and workmen, and could not tolerate anybody between himself and his foremen, and indeed he would often override a foreman's discharge of a man. Even when making the large profits we have mentioned, his own personal expenditure was a mere nothing, as he lived in the simplest way possible, and was nearly always at his works night and day. As soon as he got money he spent it on increase of works or plant. His workmen were devoted to him, and he made friends to the last amongst all grades, and by some hundred of these his funeral on Monday last at Kensal Green Cemetery was attended.

ELECTRIC LIGHTING IN SPAIN.—A correspondent of *L'Electricien* gives some account of the doings of the Sociedad Espagnola de Electricidad in a recent issue of that journal. The company, it appears, has a capital of 20,000,000f. (say £800,000), M. Dalman, of the firm of Dalman and Sons, of Barcelona and Madrid, opticians, &c., being the managing director. M. Dalman was the first to introduce the Gramme machine into Spain, some eight years ago. The company's works at Barcelona, in the Calle del Cid, utilise 140 horse-power in the production of Gramme machines, and arc lamps, Maxim lamps (of which latter they can turn out 1,000 per day), and Kabath accumulators. About 200 workmen are employed. The company are erecting a central station, which will occupy some 7,000 square metres, close to the centre of the town, where they will have at their disposal 2,000 horse-power. They use Root boilers and Corliss engines. The company has recently erected 15 Gramme arc lamps on the quays of the town. They are also making provision for a large central station in Madrid, and have several lights already going there in cafés and other places.

METHODS OF EXCITATION AND OF AUTOMATIC CONTROL IN DYNAMO-MACHINES.

BY PAGET HIGGS.

The method of exciting the electro-magnets of dynamo electric machines usually adopted is that due, as far as present evidence goes, to Hjorth. It is too well known to need description, and is generally termed the method of "mutual accumulation." The principle of mutual accumulation extends, however, to all methods whereby the electro-magnets are excited by the armature of the same machine. This method, illustrated diagrammatically in Fig. 1, may for the purposes of this paper be termed the *ordinary* method; the electro-magnets M are in the same circuit as the armature A. LL^1 are the terminal screws of the machine.

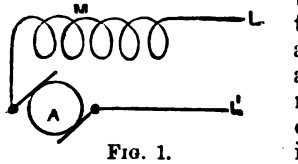

FIG. 1.

There is an earlier method of exciting the magnets of machines, due to Sinsteden (*Pogg. Ann.*, 1851, vol. 84, p. 186) the current circulating in the magnet-coils being wholly produced by a auxiliary machine. This is shown in Fig. 2, but the auxiliary machine is omitted. The method is to-day largely used in connection with some so-called regulating systems, the regulation being effected in the main or armature circuit by alteration of the strength of the exciting current from the auxiliary machine. Such a system of regulation needs the use of a regulator in the main circuit controlling the introduction and withdrawal of resistance in the circuit of the auxiliary machine, as well as a second machine, a somewhat costly and clumsy arrangement, likely to introduce error or failure from the multiplication of the apparatus.

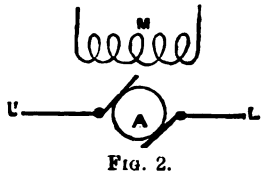

FIG. 2.

Very recently M. Marcel Deprez has introduced a combination of these two methods in a system wonderful for its simplicity and for the clearness of its elucidation and its numerous applications. M. Deprez has not only demonstrated the theory of his arrangement to be applicable in practice, but has carried out several important applications. This system, Fig. 3, consists in winding the electro-magnet inductors with two equal wires side by side; one circuit is traversed by a current produced by an auxiliary machine, the other by the current produced in the revolving armature of the machine itself. The first circuit is used to maintain an "initial field," the second develops the full power of the inductors in the usual fashion. To maintain the electromotive force constant, a certain speed is only further necessary to be found; to maintain the quantity of current constant the inductors are arranged in a derived circuit from the main circuit, and the same speed gives the desired result, however, in either case, the resistance of the external circuit may be varied.

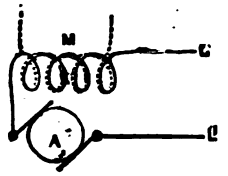

FIG. 3.

Thus, without any auxiliary apparatus whatever, except an exciting machine, besides the ordinary dynamo, M. Deprez's system affords a perfect system of regulation, and one by which, with simple manipulation of a commutator, either the electromotive force or the quantity of current may be kept constant at will, no matter how the resistance of the external circuit may vary.

In December, 1881, this system was fully described in the pages of *La Lumière Electrique*. In March of the same year I applied to the U.S. Patent Office for letters granted in June for an arrangement of the inductors of a dynamo machine enabling the same result to be obtained with a single machine without any auxiliary exciter. It is scarcely necessary to add that my experiments had been made long before.

Before proceeding to describe this method I would remark that Wheatstone in his early paper (1867) pointed out the considerable advantages of the "shunt" method of winding dynamo machines, an arrangement that has only recently been recognised. Mr. Edison, were it not for this manner of arranging his machines, would probably be in the same position as regards the excitation of a low-resistance armature as are most makers of electro-plating machines who have not yet adopted this way of winding. It is, in fact, the only effective manner of winding such machines; it is shown in Fig. 4. As a matter of history, it will be found that the large inductors, which now appear in the machines of the best construction, also are evident in even an exaggerated form in the machines delineated and constructed by Wheatstone, and I am able to say that this construction was not a matter of accident with him. Indeed, many of the old machines are examples of much careful thought, now claimed as modern invention. We might even refer the idea of the initial field to this category, if we accept Hjorth's (1854) description of his machine. Col. Bolton's abstract of the patent reads:—"The coiled armatures revolve between the poles of cast-iron permanent magnets, *and* of fixed electro-magnets," the principles of mutual accumulation being then detailed; and, the specification adds, "the permanent magnets may be coiled like the electro-magnets, which also will serve to make them more permanent." Here are all the requisites for an initial field, although not in a sufficiently practical form. In a specification of a patent applied for in the United States Patent Office in March, 1880, but afterwards withdrawn, I had thought of procuring an initial field by the introduction, amongst the other inductors in a machine, of electro-magnets having parts of their cores of steel, but the large dimensions required to secure practical results, and the inferior steel for this purpose to be obtained in America, early led to abandonment in favour of the previously tried idea of a combined system of electro-magnet inductors.

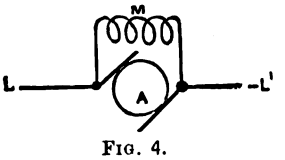

FIG. 4.

This combination system I have arranged as follows:—A dynamo machine is selected, having preferably several electro-magnets to a magnetic pole of the inductors of the machine. [Or if the machine is one in which there are more than one pair of poles, the distribution to be described is made between the several sets of magnets, as will be readily imagined.]

Some of these electro-magnets are included in a shunt circuit between the armature poles of the dynamo machine, and the *remainder* are arranged in the main circuit. The proportion of the distribution will vary according to the purpose and the electromotive force of the machine.

Fig. 5 is a diagram of the machine thus arranged.

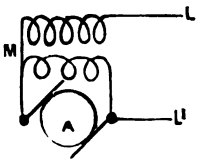

FIG. 5.

Accepting the proof given by M. Marcel Deprez (*La Lumière Electrique*, tome VI., pp. 309) as applying to this case, although, owing to the introduction of another variable, the integration can only be done by parts, we see that we have an initial field formed by the magnets of the shunt-circuit, and it is easy to find that speed for which the potential difference in the main circuit shall remain constant, however the resistance may vary. But the variation of the speed necessary to establishing this condition causes a variation of the initial field, and therefore modifies very considerably the analytic solution of the problem. Yet in practice a system of coned pulleys offers simple and easy answers to the question of what is the right speed. Referring to the diagram employed by M. Marcel Deprez, and, bearing in mind that in this case decrease in speed means a decrease in quantity of current producing the initial field as well as in the potential or ordinate corresponding to that quantity of current, it is easily perceived that a few more sets of readings have to be preserved of the E.M.F. corresponding to the several quantities of current, and that

Digitized by Google

is the sole practical trouble which has only once to be incurred by the builder of the machine to find the proper speed.

If the inductors are so arranged as to include all those relating to the north polarity of the machine in one circuit, and all those giving the south polarity in the other circuit, a very curious state of things accrues. For we know that, if we excite only one pole of the inductors of a dynamo machine, we get practically no current, and that if we excite the poles unequally, we do not get the full force of the current due to equal excitement of both poles. The cause is easy to see. Now, suppose we arrange our shunt system of inductors to give a certain magnetic field due to a certain product of current and number of convolutions in the inductors, if the magnetic field corresponding to the other pole and circuit be not maintained at or very nearly the same intensity, the current given by the machine will practically cease. That is, it is practicable to construct on this principle a machine that shall give a current only when the outer circuit is in a normal condition; and it is unnecessary to dwell upon the enormous advantages under some circumstances to be obtained from this capability without the help of any auxiliary whatever.

Beyond the advantages that either with lamps or with motor machines driven from a machine arranged on the combined shunt and main circuit inductor principle, each lamp or motor is absolutely independent of any other on the same circuit system, so that it can be extinguished or stopped, lighted or started, without affecting the others. There is another benefit derived. Every one who has had to deal with large dynamo machines arranged on the ordinary plan must have felt, when driving with an engine that has very small surplus power, constant anxiety as to what would happen if the circuit were suddenly and wholly broken. A very serious accident once occurred to me under these conditions, resulting in nearly utter destruction of the engine, for the governor, although somewhat better than the average, did not respond with the lightning rapidity required by the electric current. In the case of the combined system, the load is never wholly removed, and the engine has the small but necessary check. A similar source of danger occurs with the simple shunt system alone, when the outer circuit is put on short circuit, as by the failure of a lamp, for then all the current is drained, as it were, from the electro-magnets, and the machine ceases its functions.

A method of distributing electrical energy has been recently patented by Professor John Perry. It consists in combining with the dynamo machine one or more magneto-electric machines or other sources that will produce in a circuit an electromotive force constant and independent of any other electromotive forces in the same circuit. When the main wires are arranged in parallel arc with an ordinary dynamo there is introduced into the main circuit a magneto-electric machine or battery, producing a constant electromotive force equal to that which ought to exist between the supply and return mains. The speed of the dynamo-machine ought to be such that the electromotive force created is proportional to the current circulating in the field magnets, or, in other words, the field in which the armature rotates ought to be proportional to the magnetising current. When a shunt-dynamo is used, Professor Perry prefers to place the magneto-machine in a part of the circuit which is quite outside the machine, that is, in the main circuit, so that the current passing through it is that which goes to the supply cable. These arrangements apply when the lamps are in parallel arc; when the lamps are in series, a shunt-dynamo machine and a magneto machine are employed. Let the shunt part of the dynamo be called M, and the armature circuit A; the two ends of A and of M are the same, and may be called the binding screws of the machine. If these binding screws are joined to the two ends of a circuit containing a series of lamps, and there be introduced a magneto-electric machine in the part A or in the part M, or if we have a magneto-machine in A and another in M, a certain speed can be given to the machine as will cause it to deliver a constant current of electricity through the external circuit, however the resistance of that circuit may vary. The constant current is that which the magneto machine or machines would produce in a circuit whose total resistance is equal to the resistance of A.

There are thus three methods of absolute control afforded the electrician, that of M. Marcel Deprez and that of Professor Perry, each needing an auxiliary machine or equivalent, and that which I have myself outlined here, and needing only one machine to attain practically the same end.

In recounting these inventions, I distinctly disclaim any desire to assert priority, even if it be my due; for I am convinced that that process which is the most practical will bring, at the present day, the best recompense to its inventor, whilst each described has its advantages.

In a future paper I will enter upon the more exact examination of the subject.

DETECTION OF METALLIC MASSES IN THE HUMAN BODY*

BY ALEXANDER GRAHAM BELL.

The subject of my present paper recalls a time of intense excitement and painful suspense. The long, weary struggle with the untimely death-wound—the prolonged suffering borne so bravely and well by the lamented President Garfield must still be fresh in every recollection. The whole world watched by his bedside, and hopes and fears filled every passing hour. No one could venture to predict the end so long as the position of the bullet remained unknown. The bullet might become safely encysted, but, on the other hand, recovery might depend upon its extraction. The search with knife and probe among vital and sensitive tissues could not be otherwise than painful and dangerous; and the thought naturally arose that science should be able to discover some less barbarous method of exploration.

Among other ideas,† the thought occurred that the bullet might produce some sensible effect in modifying the field of induction of a coil brought near the body of the President, and that the locality of the bullet might thus be determined without danger to the patient and without pain; for it is well known that induction can be powerfully exerted through the human body without producing any sensation whatever.

Upon the Balancing of Induction.

The influence that is exercised upon induction by metallic masses has formed the subject of numerous experiments by different investigators; and the principle of balancing the effects of induction on one portion of a circuit by equal and opposite effects produced upon another portion has been utilised in nearly all such investigations.

The earliest form of induction balance for this purpose appears to have been devised in Germany by Professor Dove,‡ about the year 1841, and a good description of it in the English language may be found in De la Rive's *Treatise on Electricity* (1853 edition, Vol. I., pp. 418-433)§.

Another and superior arrangement for the same purpose is the well-known induction balance of Professor D. E. Hughes||.

The static induction balance of J. E. H. Gordon,¶ though primarily intended for experiments upon specific inductive capacity, might also, perhaps, be employed in the same class of investigations.

My own attention was directed to the balancing of induction a number of years ago by the disturbing noises produced in the telephone by the operation of telegraphic instruments upon lines running near the telephone conductor.

The difficulty was remedied by using two conductors instead of one, and by so arranging them with reference to the disturbing wires that the currents induced in one of the telephone conductors were exactly equal and opposite to those induced in the other. In this way an induction balance was produced and a quiet circuit secured for telephonic purposes. This method was patented in England in November, 1877, and during the whole winter of 1877-8 I was engaged in London upon experiments relating to the subject.

In the course of these researches I made frequent use of flat spirals of insulated wire, like those employed by the late Prof. Henry** in his experiments upon induction.

My method was to pass a rapidly interrupted voltaic current through one flat spiral while I examined its field of induction by means of another flat spiral connected with a telephone. The currents induced in the latter coil produced a musical tone from the telephone.

At every point in the field of induction it was found that by turning the

Digitized by Google

plane of the exploring coil a position of silence could be obtained, and another of maximum sound, the two positions making a right angle with one another.

It was also noticed that when a position of silence was established a piece of metal brought within the field of induction caused the telephone to sound. This effect was most marked when the two flat spirals were in close proximity, and were arranged with their planes parallel, as shown in Fig. 1.

When a silver coin, such as a half-crown or florin, was passed across the face of the two coils, the silence of the telephone was broken three times. The instrument emitted a musical tone when the metallic disc passed the

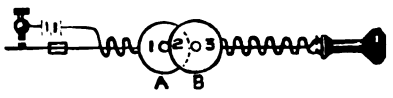

FIG. 1.

points marked 1, 2, and 3 in the illustration, but the loudest effect was produced when the coin crossed the area marked "2," where the two coils overlapped.

After my return to America I embodied these and other results in a paper "Upon New Methods of Exploring the Field of Induction of Flat Spirals," which was read before this association at the Saratoga meeting in August, 1879.

Practical Application.

While brooding over the problem of the detection of the bullet in the body of President Garfield. these experiments made in England returned vividly to my mind. It seemed to me that if the overlapping area "2" of the two coils shown in Fig. 1 could be brought over the seat of the bullet without disturbing the relative positions of the coils, the telephone would probably announce the presence of the bullet by an audible sound.

A crude experiment was at once made to test the idea. A large, single-pole electro-magnet (the core of which was composed of a bundle of fine iron wires) was used in place of coil A (Fig. 1), and a small coil of fine wire taken from a hand telephone was arranged a little to one side of the pole to represent coil B. The small coil being connected with a telephone, a battery current was passed through the coil of the electro-magnet, and the battery circuit was made and broken by an assistant.

Under these circumstances a much better balance was obtained than could possibly have been anticipated. Upon now bringing a leaden bullet near the small coil, a distinct ticking sound could be heard from the telephone each time the battery circuit was made and broken.

Being absent from my laboratory, and without facilities for proper experiment, I communicated my ideas to Mr. Charles Williams, jun., of Boston, manufacturer of electrical and telephonic apparatus, who kindly placed the resources of his large establishment at my service, and at great personal inconvenience delegated his best workmen to attend to my experiments.

Upon attempting to devise an appropriate form of apparatus for the special purpose in view I saw that there were great practical difficulties in the way of utilising the arrangement shown in Fig. 1, and it occurred to me that the apparatus of Professor Hughes might, perhaps, be employed with more advantage as the basis of my experiments. In the ordinary form of Hughes's induction balance four coils are used, as shown in Fig. 2. Through the agency of a Hughes microphone the ticking of a clock is

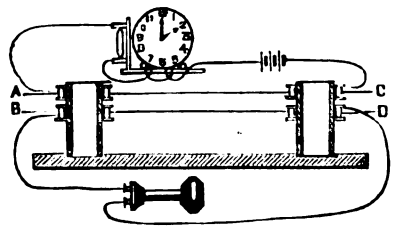

FIG. 2.

made to create an electrical disturbance in the voltaic circuit containing the two primary coils A C, and a corresponding disturbance is produced by induction in the two secondary coils B D connected with the telephone. If the connections are so arranged that the currents induced in the telephone circuit by the coils A C are in the same direction, the ticking of the clock is heard very plainly, but if they are in opposite directions no sound is perceived.

In the latter case the action of one primary coil, A, opposes that of the other, C, and an electrical balance results. If now a piece of metal is brought near one pair of coils (say A B) the balance is disturbed, and the ticking of the clock is audible at the telephone. The arrangement of the coils A, B, C, D was the point to be studied, the microphone attachment being of no importance in the combination; for it is well known that a rheotome to break the primary circuit completely at intervals can be substituted for the microphone with advantage.

It seemed to me that two of the coils A B in the Hughes induction balance might be attached rigidly to a wooden handle, so as to be moved over the seat of the bullet without changing their relative positions, and that all the adjustments necessary might be made on the other pair of coils, which need not be moved from their place, and would not, therefore, be liable to disarrangement. If a single pair of coils were to be used as in Fig 1, they must be adjustable one upon the other. But if during the course of exploration the coil B (Fig. 1) should be moved from its proper position even to the extent only of a small fraction of a millimetre, the balance would be disturbed and the exploration might have to be stopped in order to adjust the apparatus. These considerations led me to the conclusion that some modification of the Hughes induction balance was most suitable for my purpose, and I immediately commenced the construction of such an apparatus.

Suggestions Tested.

Just at this time I learned from the newspapers that Professor Simon Newcomb, of Washington, had the idea of using a magnetic needle to indicate by retardation of its rotation the proximity of the bullet in the body of the President, and I telegraphed to Professor Newcomb the offer of my assistance in carrying on experiments, knowing the comparative difficulty he would experience in having apparatus made in Washington.

At his suggestion I tested the point whether the rotation of a leaden disc and of a leaden bullet underneath a delicately suspended magnetic needle would cause a deflection of the needle.

The disc occasioned a deflection, but the bullet produced no sensible effect. I telegraphed the result to Professor Newcomb, and at the same time took occasion to inform him of the hopeful results I had obtained with the crudely-constructed induction balance referred to above.

I was much gratified by his immediate appreciation of the experiment. He telegraphed that he thought an induction balance promised a much more hopeful solution of the problem than his own method, and encouraged me in every way to continue my experiments.

This appreciation determined me to proceed to my laboratory at Washington, where I was accompanied by Mr. Sumner Tainter, who was anxious to assist in such a cause. I learned from Professor Newcomb that Mr. George M. Hopkins, of Brooklyn, had independently suggested the use of Hughes' induction balance, and had made experiments in Brooklyn, the results of which were published in the *New York Tribune* on the 11th of July, 1881.* Mr. J. Stanley Brown (private secretary of President Garfield) kindly handed to me the letters he had received from Mr. Hopkins,† and also a Hughes induction balance like that shown in Fig. 2, which Mr. Hopkins had forwarded to the Executive Mansion for trial.

This apparatus was at once tested in my laboratory, with results slightly better than those I had obtained in Boston.

My Boston apparatus did not give a greater hearing distance than 3 cm., whereas with the Hopkins apparatus I could distinguish effects at a distance of 3·75 cm.

Two of Mr. Hopkins's coils (A B, Fig. 2) were then fastened upon a wooden handle to form an exploring instrument, and the whole apparatus was arranged for immediate use in case of any necessity arising for an experiment upon the President. I set myself in communication with Mr. Hopkins, and requested his assistance and co-operation, and in reply received through Private Secretary Brown the following account of further experiments:

"60, Irving-place, Brooklyn, July 16, 1881.

"Mr. J. Stanley Brown:

"Dear Sir: I have made two new instruments on plans differing from that sent, but they yield no better results. The first consisted of two oblong coils arranged at right angles to each other, thus:

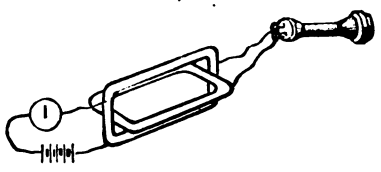

FIG. 3.

"The outer coil being of coarse wire (No. 18) placed in the primary circuit, the inner coil being of very fine wire (No. 36) and connected with a telephone. The parallel currents traversing the wires neutralised each other, and no audible effects are perceived in the telephone, but on presenting a metallic body to the instrument upon a line bisecting the angle between the coils the clicking in the telephone is heard.

"This instrument possesses only one advantage over that sent, and that is that it requires no adjustment.

"The other instrument consists of two large coils of very fine wire (No. 36) placed upon opposite sides of a coil of coarse wire (No. 16), the fine coil being connected so that the induced currents neutralise each other, thus:

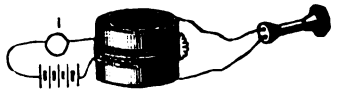

FIG. 4.

"I am sorry to be obliged to say of this as of the other, that it is no more sensitive than the one sent. To produce the best effects from the instrument which you have it will be necessary to use all the battery power possible without burning the coils, and two receiving telephones of the best construction must be used.

"As I stated in the first instance, if the ball is more than two inches deep, I think it cannot be located by this means.

"If larger coils were used the instrument might be operative at a greater distance, but the area indicated as containing the ball would be so large that the result would be indefinite and without value.

"Hoping that Professor Bell will be able to succeed, I remain,

"Yours very truly, "Geo. M. Hopkins."

Professor Hughes, of London, England, Professor Trowbridge, of Harvard College, Professor Rowland, of Johns Hopkins University, and other authorities were consulted by telegraph as to the best theoretical form of induction balance for the purpose required, while empirical experiments were being carried on under my direction in my laboratory at Washington by Mr. Sumner Tainter: in the electrical workshop of Davis and Watts, in Baltimore, by Mr. J. H. C. Watts, and in the establishment of Mr. Chas. Williams, jun., in Boston, by Mr. Thomas A. Gleason. To test the influence of size of coil an instrument was constructed in which the coils were no larger than the bullet for which we sought (as had been suggested

* See Appendix, note 2.

† See Appendix, notes 3 and 4.

Digitized by Google

by Professor Newcomb),* and experiments were also made with the enormous coils used by the late Professor Henry in his researches upon induction, which were kindly lent to me for the purpose by the Smithsonian Institution, but neither the small nor the large coils produced more satisfactory results than those we had already obtained.

To test battery power, 20 enormous Bunsen elements, which had formerly been used to light the gas at the Capitol, were placed at my disposal by Mr. Rogers, electrician of the Capitol, but while great electromotive force was evidently of use we derived no advantage from such a battery as this.

To test the influence of speed of interruption, Mr. Marean, superintendent of the Western Union Telegraph Company in Washington, kindly lent us an electric motor, by means of which we were able, with the aid of a rotating commutator, to obtain interruptions of the primary circuit of all rates up to 600 interruptions per second†, and we found that the more

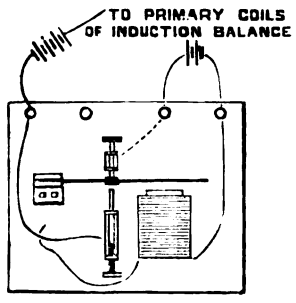

FIG. 5.

rapid the rate of interruption the more distinct was the sound in the telephone. The hearing distance, however, was not proportionately increased. The automatic interrupter, (shown in Fig. 5,) yielding about 100 interruptions per second, gave as good results as any, and was much more convenient. This interrupter was therefore afterwards used exclusively in our experiments.

The theoretical form of coil suggested by Professor John Trowbridge ‡

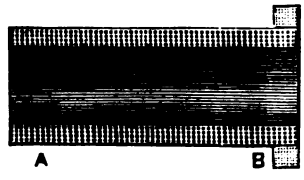

FIG. 6.

was substantially the same as that proposed by Professor Rowland§, and is shown in Fig. 6

The arrangement was quite sensitive to metal placed in the interior of the coil, but the hearing distance for a bullet external to the coils was no greater than before.‖

Professor Hughes¶ proposed to have two flat superposed coils wound on a single reel, so that the two coils should form a single one as regards their relative distance; and Mr. F. T. Bickford, Washington correspondent of the *New York Tribune*, suggested winding two wires side by side into a single coil, so that the relative distances of the wires from the bullet should be absolutely the same. Mr. Charles E. Buell** and Dr. Chichester A. Bell†† proposed to determine the depth of the bullet beneath the surface by causing a similar bullet to approach the balancing coils until silence was restored; the secondary bullet, it was presumed, would then be at the same distance from the balancing coils as the embedded bullet from the exploring coils.

The results of all the experiments so far made were unsatisfactory. I had tried everything that had been suggested, but 4 cm. remained the extreme limit of audibility for a bullet like that which had struck the President. Even when such a bullet was flattened by being fired against a board, and was presented with its flat side towards the coils of the explorer—the most favourable mode of presentation—no better result was obtained.

Original Experiments.

In the theoretical arrangement recommended by Professors Trowbridge and Rowland (Fig. 6) the primary coil A was of smaller diameter than the secondary B. This had given us no better effects than the ordinary form of Hughes balance (see Fig. 2), in which the two coils A B were of equal diameter. We then tried the effect of making the primary coil A of greater diameter than the secondary B (see Fig. 7); and in this case we appeared to obtain an increase of hearing distance. Five centimetres (two inches) was, however, the utmost limit reached when, on the 19th of July, Mr. J. Stanley Brown and Dr. Woodward visited my laboratory and witnessed some experiments. No difficulty was experienced in detecting a bullet held in the mouth by passing the exploring coil over the cheek: and the presence of a flattened bullet held in the clenched hand was also readily determined. Dr. Bliss, Dr. Reyburn, and Surgeon-General Barnes visited the laboratory next day, and expressed themselves as very hopefully impressed

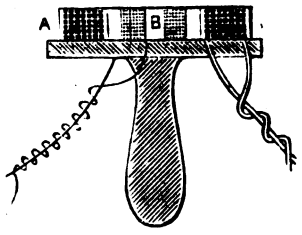

FIG. 7.

by the experiments. These were subsequently repeated in the surgeon's room at the Executive Mansion for the information of Dr. Frank Hamilton and Dr. Agnew, who also seemed favourably impressed.

Such opinions from the surgeons in attendance upon the President, and the continued interest shown by Professor Newcomb, encouraged me to proceed with the experiments.*

It was now determined to test the effect of each convolution of the primary coil, so as to arrive empirically at some idea of the best shape of coil. For this purpose Mr. Tainter constructed the instrument shown in Fig. 8. Circular grooves were turned in two boards, one of which is

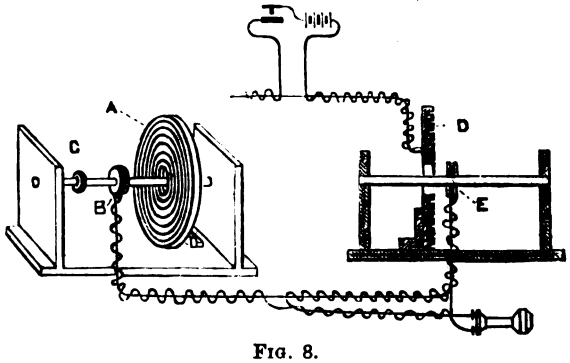

FIG. 8.

shown in perspective at A, and the other in section at D. An insulated copper wire could be pressed into any of these grooves so as to give the wire an exactly circular shape of known diameter, and the two ends were passed through an orifice in the back of the board, making connection with a similar ring of wire in the other instrument, as shown. A small secondary coil B of fine wire, which could be moved with moderate friction upon the horizontal rod, was connected to another similar coil E, and to a telephone; and a small brass ring, C, which could also be moved along the horizontal rod, was used instead of a bullet to disturb the balance.

In making an experiment with this apparatus the secondary coil B was first placed within the primary ring and in the same plane with it, and the balancing coil E was adjusted to produce silence. The brass ring C was then moved along the horizontal rod until the balance was sensibly disturbed and the relative distances of the coils and the brass ring were noted.

(TO BE CONTINUED.)

THE FAURE ELECTRIC ACCUMULATOR COMPANY.

An extraordinary general meeting of the shareholders of this Company was held at the Cannon-street Hotel on Monday last, Sir A. J. Otway, Bart., M.P., in the chair.

The SECRETARY (Mr. Herbert Canning), having read the notice calling the meeting,

The CHAIRMAN said: Gentlemen, you have heard the notice read convening this meeting, which I need scarcely say is one of considerable importance to all of you who are interested in the Faure Company. Now, certain contracts have been provisionally signed by the Board of the Faure Company. I say provisionally, because those contracts have no validity whatever until you should ratify and approve them. On your approval and ratification they will become good and valid contracts, but not till then. These contracts have been drawn in pursuance of the policy indicated in a speech made to you by M. Philippart, which was rendered into English on two occasions—a very clear statement, I must say—and to which policy you on two occasions gave your adhesion. On the second occasion I felt bound to tell you that the Board, not concurring in the proposed procedure, would not be able to continue their functions as administrators of the Company, and that they would ask to be relieved from the office they now hold, and that others should be put in their places. They also thought that those appointed to fill their places should be gentlemen who were in entire accord with M. Philippart in the policy he was about to carry out, and as the working of the Company would henceforth be carried out in France,

* See Appendix, note 5.

† Mr. Sumner Tainter has since made an apparatus operating in a similar manner, by means of which he has obtained as many as 4,000 interruptions of the circuit per second.

‡ See Appendix, note 6. § See Appendix, note 7.

‖ The balance obtained was not quite perfect, and we have since discovered that the insulation of the wires of one of the secondary coils was defective.

¶ See Appendix, note 8. ** See Appendix, note 9. †† See Appendix, note 10.

* I desire specially to express my gratitude to Dr. Frank Hamilton for words of encouragement spoken at a later date, when sympathy and encouragement were greatly needed.

and not in England, I thought that they should be rather French than English directors. Well, now, M. Philippart, after the meeting, entered into certain arrangements with which I have no concern. He will have an opportunity of addressing you, and I am perfectly certain that he will explain what he has to say in a clear manner to you. He entered into certain arrangements, which were limited, as he informed us, as to time. The consequence was that, unless those arrangements were to fall through entirely, and the prospects which appeared to M. Philippart so bright were to be dispelled, it was necessary that those agreements should be signed provisionally by the Board. Hence, that which may appear an inconsistency, but which is not so in point of fact, is perhaps to be found on the part of some of you who hear me, namely, that the signature of some of the members of the Board is given to contracts of which they do not themselves approve. But that was done because time was the essence of this matter, and under the condition that they should be entirely of a provisional character. Now, I am not here to express an opinion on the contracts themselves. They will be read by our solicitor, a most able and experienced gentleman, and M. Philippart will address you also. Nor am I about to enlarge on the feeling of the Board in regard to them. They are matters upon which gentlemen very often differ. A mode of carrying on business may commend itself to some gentlemen that is not so well thought of by others. I may also remind you again of the reason I gave you on the last occasion on which we met that the mere fact of the business being transferred to France, to my mind is quite sufficient to relieve us of the position of being useless in London. It is not a position that would suit any of my colleagues or myself to fill a useless purpose, and the operations of the Company being transferred to France, that would be the result if we retained our positions. That being so, it is unnecessary for me to enlarge on the precedure, and our absence of concurrence therein. There was one condition I thought only essential to make, and I adverted to it on the last occasion. I said I would not leave my place at the Board till I was certain that that which I considered a sort of honourable engagement we had taken towards the shareholders had been fulfilled, or unless means had been provided by which it should be and must be fulfilled. I understand from our solicitor that those means are now provided. I allude to the question of supplying every shareholder who has applied for the same with one fully paid up share in regard to two of his present shares with £2 paid thereon. A certificate will be lodged embracing the aggregate number of shares. It has not been possible to divide these shares at the present moment so as to give to every shareholder his one share fully paid up for the two he holds, but a certificate of the aggregate amount necessary to do that will be consigned to the custody of Mr. Campbell, the solicitor, and myself if you like it, as trustees for the carrying out of this operation, and I understand that at the latest, on the 2nd day of January, M. Philippart will be prepared with all the certificates then divisible among the shareholders who apply for them. Certain formalities will be gone through. A letter will be sent to every shareholder. I understand that this is the process—that it will be intimated to him how he is to apply for his certificate, and thereupon one fully paid up share will be given to him in exchange for every two he now holds. When that is done, all I can say is that I shall consider that our business as administrators terminates. I must say that we have had as little agreeable and as anxious a time as it was possible for any gentlemen to have. We have had a great many difficulties to contend with. It is not very pleasant for gentlemen who pursue a business on one line to be suddenly called on to pursue it on other lines. I am not at all ashamed of the operations we have carried on. I think they redound very much to the credit of the Faure Company, and have tended very much to popularise the accumulators in this town, and I can only think that the future of the accumulator will be very great. I cannot help regretting that it will not be in England that its great success will be achieved; but there are conditions, no doubt, more favourable for the accumulator in France than in this country. They will suggest themselves to you probably, such as the price of coal, the consumption of gas, and the price of gas, and those conditions make it more profitable in France than in this country; that, however, is not our concern. We intended to be an accumulator company—an industrial company. That was our wish. By the decision of the shareholders that is altered, and the business is transferred to another country. Our services are rendered useless, and we now seek our right to retire from our places at the moment we can. I am not aware that that cannot take place almost immediately. We cannot leave the Company utterly without any one. We have one director who will remain. M. Philippart will remain on the Board, and it will be necessary to nominate some other director. These two gentlemen forming a quorum will be able, I hope, to find some satisfactory colleagues to carry on the business of the Company. I shall be very glad, as this will be the last occasion we shall have of meeting you (at least on this side of the table), if any gentleman present will interrogate us on any matter on which he may desire information, because we should like to have the opportunity of answering him. We are in this fortunate position at least. We have nothing to conceal, and we should like to have this opportunity of answering any gentleman's questions concerning the Company, or the way it has been carried on; and we should like to hear any remarks that they may have to make. I shall now ask Mr. Campbell, the solicitor, to read to you those agreements, and explain them, and then M. Philippart will inform you how he intends to carry them out, and what view he takes of the future prospects of the Company. Mr. Campbell will now read first M. Philippart's statement, and then you will hear the agreements read.

Mr. CAMPBELL (the Company's solicitor): This is a sort of prelude to the agreement, and I think the agreements will be more easily understood. This is M. Philippart's statement:—Gentlemen, the contracts which are to-day submitted for your approval were only signed on Thursday last. In my opinion they might and ought to have been signed sooner, and without the reservation of your approval, for they only carry out the programme which you unanimously approved on the 6th November last, and the particulars of which you received with enthusiasm at our meeting on the 4th of this month. I cannot now enter into all the details of these contracts, for it would take up too much time, and would, besides, be unwise in our common interest, but I wish again to touch upon their salient points in order that you may seize the advantage we shall derive therefrom. By the first of these contracts the Storage Company returns to you your 20,000 fully paid up ordinary shares, which were allotted to them by the agreement of the 6th and 7th of July last, and the Société la Force et la Lumière surrender as well the 50,000 deferred shares. On the other hand we cede to the Storage Company definitely and entirely the interest which we retained in the Faure, Sellon, and Volckmar patents for the United Kingdom. By the second and third contracts our Company obtain possession of about 92 per cent. of the Faure-Sellon and Volckmar patents for France and the French colonies. In virtue of those contracts this interest will be represented by preference and ordinary shares of the French Electrical Power Storage Company, which company possesses the exclusive right to the exploitation of those patents. Our intention is to sell some of these shares, and to employ the proceeds of those sales in the purchase of the Faure-Sellon and Volckmar patents for other portions of the Continent, reserving the balance either to be distributed to you in whole or in part as dividends, or to be retained by our Company, as may be deemed most advantageous for you. After the fulfilment of these contracts, and when the 40,000 ordinary shares of our Company are fully paid up, the following will be our financial position: Of the 80,000 ordinary shares of our Company 47,000 only will be issued, 33,000 unissued. Our assets will consist, as I have already told you, of an interest representing about 92 per cent. of the Faure, Sellon, and Volckmar patents for France and the French colonies and we shall, further, have available a sum exceeding £100,000. I trust you will be pleased to learn that after the execution of these contracts we expect to be able to pay in the course of the month of January next a dividend at the rate of 10 per cent. per annum from the date of issue upon the £2 paid of our 40,000 ordinary shares. Let me add that I have cogent reasons for stating that during the month of February next we shall be able to declare a further dividend of at least £4 a share, and that I hope for still greater things. It is, of course, understood, gentlemen, that the execution of these contracts assures the fulfilment on the due date of the engagement taken by the Société la Force et la Lumière with those among you who have accepted this offer. Your chairman and his colleagues deemed it right to retain their seats till this engagement was fulfilled. I have no wish to underrate in your eyes the services of my colleagues, but I do wish to take this opportunity of stating that the Société la Force et la Lumière never had any idea of departing from this undertaking; but that, on the contrary, it was well pleased that so many of you accepted its proposal, and that it is of opinion that it has done a good business which it would on no account relinquish. Even were this not the case I have the right to say on my own behalf and on that of my friends that your interests will be as well looked after by us as by others. Certainly we are not infallible, and we may make mistakes, but you have, at any rate, the guarantee that should we do so we shall ourselves be by far the greatest sufferers. Allow me once again to touch on the value of the patents we possess, and enter into a few details in connection therewith. On the 6th of November last I said to you—1st, that the accumulator was as great a necessity for electricity as was the gasometer for gas; 2nd, that the Faure Sellon and Volckmar accumulator was so far the only practical and economical accumulator; 3rd, that we had the best reasons for believing that it would not be superseded. I do not believe, gentlemen, that any one will even now attempt to controvert the two first assertions, and, in support, thereof, I am pleased to be able to tell you that the company, which had purchased the Donnithorne accumulator, of which we had heard so much, has entirely abandoned it, and has applied to the Storage Company to furnish it with all the accumulators it requires. Indeed, the Storage Company cannot nearly execute all the orders it receives, although producing 250 tons of accumulators monthly. As to the third, it will be said that no one can put a limit on the progress of science. The whole question to be solved is the extent of progress which is required to attain perfection, and consequently the nearer we attain perfection the less room will there be for improvement, and, therefore, the less we shall have to fear. To arrive at the relative value of an invention three things have to be considered. First, prime cost; second, the cost of maintenance; third, yield. Now what progress still remains to be made under these heads? Prime cost: Our accumulators are now made exclusively of plates of lead, cast with holes in them, in which holes we place red lead or oxide of lead. These plates, after having been formed by the passage of an electric current, lasting 100 or more hours, are placed in a wooden box lined with sheet lead, and separated from each other by india rubber bands. The first cost of the material is from £15 to £16 a ton, and that of the labour about an equal amount. What can be discovered simpler or more economical? Maintenance: Half the plates composing an accumulator are called positive and half negative. Experience proves that the negative plates do not wear out in working. The positive plates only, after a greater or less number of months' work, become unfit for working, owing to the entire peroxidation of the plates. Thus the maintenance of the batteries renders the replacing of half of the plates necessary every year on a most liberal estimate. But this replacing simply entails a question of labour, seeing that it is only necessary to grind up these peroxidised plates, and with this ground peroxide to fill up the holes in the new lead plates, unless indeed, which is probable, this peroxide is sold at a much higher price than the lead or red lead, in which case the maintenance of the accumulator will become a source of profit instead of a source of loss. It is clear, therefore, that both from the point of view of cost of maintenance and from the point of view of prime cost, there is little room for improvement. Yield: Eighteen months ago Sir W. Thomson certified that the first Faure batteries which were subjected to experiments by him gave a yield exceeding 75 per cent. Six months later our eminent electrical engineers, Messrs. Ayrton and Perry, certified a yield of over 80 per cent., and I am satisfied that to-day, with the good system of charging and discharging, we can attain a yield exceeding 85 per cent. Such being the case, am I not justified in telling you, gentlemen, that we need not fear more from the future than from the past?—that the progress we have made during the late 12 months is a guarantee of that which we shall continue to make? Further, I do not lose sight of the fact that any improvements made by others will belong to us, and will remain useless in the hands of the inventor so long as our patents are in force. You see, gentlemen, therefore, on what a solid basis our confidence in the future of our Company is founded.

Mr. CAMPBELL, after the reading of the foregoing statement, went on to describe the effect of the three agreements.

The CHAIRMAN: It would be interesting to the meeting that Professors Ayrton and Perry should make some observations to you on some technical points with regard to the result of certain experiments they made last

Digitized by Google

Saturday with the Faure-Sellon-Volckmar accumulator at the Storage Company's works.

Professor AYRTON: I must preface the few remarks I am going to make on behalf of Professor Perry and myself by saying that they do not relate to this Company's commercial or financial aspect, with which indeed we are not concerned, but they merely relate to the accumulator as viewed from an engineering point of view. It must be clear to all of you that in order that success may be attained in any invention the first point that is necessary is that there shall be a good idea to work on as a basis, the second that you stick to the improvements and developments of your idea until it bears good fruit. That the Faure invention is most valuable cannot be doubted by any one, and that both at the Electrical Company's works at Millwall, as well as at the works of our own company at Paris, a vast amount of energy and enterprise has been spent in improving the accumulator is also equally clear to all who have had an opportunity, like ourselves, of seeing what has been done. The Faure accumulator, as originally made, had three defects, first, that, great as was the advance it constituted on the Planté cell, still its capacity for storing electric power was not so very large; secondly, the rate at which this power could be taken out of it was limited; and, lastly, some kind of flannel or felt was employed to keep the red lead in contact with the lead plates and prevent the plates touching one another. In all these three directions the cell has been immensely improved during the last twelve months, so that whereas we thought it an excellent result to find last December that a cell weighing, with the lead, red lead, acid, and box, about 130lb. contained electric energy equivalent to one horse-power for three-quarters of an hour, our recent tests of the Faure-Sellon-Volckmar cells show that in a gross weight of only about 75lb., consisting of lead, oxide, acid, and box, there is a store of one horse-power for one hour; further, that whereas, in December last, we regarded a steady discharge without polarisation of a third of an ampere per pound gross weight a good result, we now can obtain as much as three-quarters of an ampere per pound gross weight. Altogether, then, the electrical value of the accumulator of the end of this year is double that of a good accumulator at the end of last. If an accumulator be regarded as a kind of coal cellar, then to maintain the analogy not only must it be considered that twice as much coal can, so to say, be now stored in a cellar of fixed size as could be stored last year, but the cellar door for a particular cellar has been made twice as wide, so that the coal can be got out of the cellar much faster, and consequently much larger fires kept burning. In addition, the flannel or felt in the accumulator is now absent, so that the positive and negative plates in the box are quite distinct, they are not only "*formed*" quite separately before being put into the box, but they can be separately taken out of a complete cell and examined, and an inferior plate, if there be one, easily removed and a good one put in its place. Indeed, it is due to these great advances in the construction of accumulators that an electric boat has been able to perform regularly its successful trips on the Thames, which we, like others, have had the pleasure of witnessing. And, again, it is this more rapid discharging power of the latest form of accumulators that has enabled us successfully to employ our electro-motor to drive a tricycle, which, when weighted with one man and sufficient accumulators to store two hours' driving power, runs over a measured mile in 8¾ minutes, whereas six months ago a slow walk was all that we could accomplish. As regards, then, facility in construction and repairs, in largely increased storing capacity and rapidity of discharging power of accumulators, this year has seen a great advance.

The CHAIRMAN said they would be glad to hear any remarks from any shareholder, and to give any explanation they could with respect to the agreements.

A SHAREHOLDER: A question suggested to me is whether the law in France is more favourable than it is in this country as to locomotives.

Professor AYRTON: The use of the word "locomotive" is a misnomer. An electrical tricycle is not a locomotive, and it is a question whether it would come under the Act. I was yesterday consulting with the counsel who opposed the steam tricycle, and he told me he thought as the Act was only for a little time, and had to be renewed from time to time, that there would be very little difficulty in getting permission for electrical tricycles but not steam tricycles.

The CHAIRMAN: We cannot give you the information about the law in France. I think it is very much the same as in this country. If no one wishes any information we will put the agreement for your ratification.

A SHAREHOLDER: When we met at the first meeting to inaugurate this new policy the tone of your speech was eminently favourable to what has been adopted. It influenced the meeting very much, and I should like to put the question now, whether anything has transpired at all to alter your opinion of the character and the result of those negotiations and agreements.

The CHAIRMAN: That is a very fair question, and I shall consider it my duty to answer it. I am not aware how far the tone I took was of the character you ascribe to it, but I am perfectly certain of this, I had no desire whatever to say anything unfavourable as to the policy of M. Philippart in its general terms. Nor do I now wish to say a word unfavourable to it. Where I have been unable to concur with him is in the procedure by which he is proposing to carry out the policy. I have never been mixed up, as I have said, in my life, and I never intend to be, in any financial business, and all these various companies are not matters with which I choose to be concerned, but I have the most entire confidence in M. Philippart. I have always said that, and I do not depart from it, and this matter in his hands in France I sincerely hope will be productive of benefit to you, but it is not a matter in which I chose to be concerned.

After a few more remarks from the Chairman,

Sir CHAS. CLIFFORD said that at one time the Board thought they were going to develop the accumulator which was in their hands, and they believed it was to be productive of wonderful events in the world, but at last they found that the largest proportion of the shares (he thought two-thirds) had got into the hands of one individual and his particular friends, and when they inquired into this they found that the command, which by these means M. Philippart and his friends obtained over the Company had quite prevented, or would naturally prevent, the Board from carrying out their schemes. Moreover, those schemes were to be identified with French interests, not with English interests, and were not so much intended for the development in the Board itself of the wonderful powers of the accumulator, but were to use the accumulator for financial purposes, whereby M. Philippart would probably gain a better dividend for the shareholders, but which left to others the development of the principle. Looking to all these things, the Board came to the unanimous determination that though they were extremely pleased to work for the benefit of the shareholders and for the benefit of science, they did not think they were justified in working for the benefit of a small party, and came to the conclusion, if they could do so without injuring their interests, to resign their positions into the hands of others who knew more about the schemes likely to be introduced than they did themselves. The consequence of that determination was this meeting. He had no doubt M. Philippart was quite able to carry out the schemes he had explained. He might also say that M. Philippart and his friends were quite right in acting as they had done, believing as they did that the interest of the shareholders was very much served by the schemes they were intending to adopt. The shareholders, however, must remember that now at this meeting the Board were resigning into their hands the trust that had been reposed in them, and they resigned that trust into the hands of others over whom they should have no control. They had heard of the pleasant prospects that were before them. He hoped those prospects would be realised, but let them bear in mind not to reflect on the late directors, but to lay all the blame and award all the praise to the directors that were to follow. Let the present Board go away with a clean sheet in the favour of the shareholders, and he was satisfied.

A SHAREHOLDER wished to ask whether, in the event of the hopes held out being realised, and these large dividends being paid, those who did not consent to the conversion of their shares would be equally entitled to participation.

The CHAIRMAN: Oh, certainly, you will be rewarded by your courage.

M. PHILIPPART having addressed a few remarks to the meeting in French,

Mr. CAMPBELL interpreted them as follows:—I wish to make a very few observations in reply to what the chairman has said. It is entirely a mistake if you think we are going to enter into questions of finance, if by finance you mean a speculation. From the report read to you and the explanation of Professor Ayrton you must see that your profit must come from the use of the accumulator and the development of the accumulator, and not from speculation. I wish you to understand it is our simple intention to proceed with this matter as an industrial scheme, and only as an industrial scheme.

A SHAREHOLDER: But when we first met on this matter it was to cease to be an industrial scheme, and to be a purely financial scheme of bringing out companies and selling concessions.

M. PHILIPPART having again addressed the meeting,

Mr. CAMPBELL (interpreting) said: In speaking of it as an industrial company I point to the great extent of France, and this Company will be the owner of shares in the company which holds the accumulator for the whole of France, for which it will have the rights and privilege of manufacturing accumulators. But to supply France it wants companies in the towns who will take licenses from that Company and carry on the system of electricity in the different towns. The mother company will provide the accumulators as they may be required. In answer to another question, he said that the whole of the companies they were assisting would be limited companies, and the Faure Company would hold shares representing 92 per cent. of the mother company in France, which was a company formed under English law.

A SHAREHOLDER wished to ask whether any litigation was going on against the present directors, or those who were about to resign.

The CHAIRMAN: I was threatened with proceedings, I must say, but such matters do not alarm me much, as they generally come from those who wish to get something from you. A firm was of opinion that we had entered into contracts with them that we had not carried out. We had a different opinion on the subject. The result has been, whatever differences there were, that all proceedings, if any were seriously intended, have been abandoned. There is no concealment in the matter. We had ordered a certain number of those accumulators, and those accumulators had not been taken. There was some question whether they were quite up to what we expected, but now they will be taken as they are supposed to be good, and I hope that they will turn out well and an amount will be paid according to the agreed contract price.

A SHAREHOLDER: It appears by these contracts, if they are ratified, that the Faure Company transfer their entire business in England to the Electrical Storage Company formed in France. The Faure Company becomes French and the Storage Company English. At the last meeting the question of an extension (but not the substitution of another company) came up. Now it is an entire change of the Faure Company.

A SHAREHOLDER: If it becomes a French company what will be its status in England? Will the meetings be held in England?

Mr. CAMPBELL (the solicitor): You are an English company and remain so, and you draw your profits out of this Company in France.

A SHAREHOLDER: Will all explanations be given in England as hitherto?

Mr. CAMPBELL: Certainly.

A SHAREHOLDER: Then I suppose the new Board meetings will be in France?

Mr. CAMPBELL: The Board will always meet in England exactly as now.

The CHAIRMAN: I think we must now put the resolutions.

Mr. CAMPBELL: Then it is simply turning the notice into the resolution:—

Resolved, "That the agreement between the Faure Electric Accumulator Company (Limited), of the one part, and the Electrical Power Storage Company (Limited), of the other part, for the sale by the Faure Company to the said Storage Company of the remaining interest of the Faure Company in the patents of Faure, Sellon, and Volckmar in England, on the terms and conditions mentioned in the said agreement, and now read to the meeting; also that the agreement between the Société la Force et la Lumière, of the one part, and the Faure Electric Accumulator Company (Limited), of the other part, for the purchase by the Faure Company of the rights and interests of the Société la Force et la Lumière in the French Electrical Power Storage Company (Limited), on the terms contained in the said agreement, and now read to the meeting; and also the agreement

Digitized by Google

between the Faure Electric Accumulator Company (Limited), of the one part, and the French Electrical Power Storage Company (Limited), of the other part, for the sale by the Faure Company to the said French Company of the property in Paris belonging to the Faure Company, and providing for the Faure Company subscribing for shares in the said French Company, as provided in the said agreement, and now read to the meeting, be approved by the meeting, and that the directors be authorised by this meeting to complete and carry the same into effect."

The CHAIRMAN: I consider I have discharged my ministerial duty. I believe there are many gentlemen who approve the resolution, and I will ask some gentleman to be kind enough to propose that it be ratified.

Mr. CUSTANCE: I will move it.

Mr. GOLDEN: I will second it.

The CHAIRMAN: I am about to put this resolution. You have heard all the explanations—all, I think, that can be said on the subject—and questions have been asked and answered. I shall say no more than this, that the entire responsibility rests with you. What I hope is that it will be thoroughly successful. If you ratify this, as no doubt you will, these contracts become valid. Sir Charles Clifford has pointed out with great clearness (I do not wish to controvert any statement that we have heard) that we are not responsible for any of those statements. They come from other parties, and not from us. Mr. Custance has moved, and Mr. Golden has seconded, the proposition as read by Mr. Campbell be now adopted, by which you will ratify these various contracts.

After being put to the meeting the resolutions were declared unanimously adopted,

The CHAIRMAN remarking: Therefore there follows the ratification of the various contracts. Replying to a question, he added M. Philippart remains a member of the Board. The English directors intend, as soon as we can, to resign. We have one vacancy by our Articles of Association, and to facilitate your operations we think it right to do what we can to give effect to that which has been for the third time assented to, and we propose to nominate the French director, of whom satisfactory references will be given. You will hardly expect that I, or my colleagues, would accept any one of whom we knew nothing, and put him on the Board, having charge of all your concerns. We shall require some references as to the gentleman, and if they are satisfactory we shall nominate him to the vacant place now on the Board. He will then, with M. Philippart, who will remain on the Board, have power, two forming a quorum, to fill up the remaining vacancies. If they think it right to appeal to the body of the shareholders to determine, that will be for them, not for us.

M. PHILIPPART again addressed the meeting in French, his observations being interpreted by Mr. Campbell as follows:—In the month of February you will be called together to approve the names of the directors whom it is proposed shall follow the present Board.

A SHAREHOLDER asked if there was no hope of inducing the present Board to accept seats.

The CHAIRMAN was afraid not. In reply to a further question, he said he held as many shares as he always held, but all he hoped was that he had secured by the scheme a very satisfactory exchange.

Sir CHARLES CLIFFORD said all the directors had acted exactly in the same way.

A SHAREHOLDER: Have you transferred your interest in the new company?

The CHAIRMAN: I do not understand you.

The SHAREHOLDER: I gathered from the first meeting that your interest would be transferred.

The CHAIRMAN: I took originally one hundred shares. I hold those one hundred shares. I have no intention to part with my interest in the company, but I have accepted the arrangement by which fifty fully paid-up shares are offered me in exchange for a hundred with £2 paid. There is no more business before us.

Mr. STAPLES moved, and Mr. TURNER seconded, a vote of thanks to the Board of Directors, the Chairman, and M. Philippart, which was cordially agreed to.

The CHAIRMAN in reply said: As this is the last occasion we shall meet, I beg to thank you very sincerely for the vote which you have just passed. The gentleman who proposed this vote said no more than the truth when he stated that we had had considerable difficulties. I have found myself for some months past in the most difficult position I have held in my life in reconciling the great conflict of ideas. But I do believe every one has wished to do what he considered best for the Company. M. Philippart has a very large interest, and has always said that no one has so large an interest as he has in the prosperity of the Company. I may add that I have been surrounded by very able colleagues, men who have always given me their support on every occasion, and therefore we have been able to get out of our difficulties without any greater disturbance than was absolutely necessary. I join with you now in trusting sincerely that all the bright prospects held out will be realised, and if so you will owe M. Philippart a deep debt of gratitude. I consider then that he will have done great things for the Company.

M. PHILIPPART said: The only way I can thank you is to earn for you the dividends I have promised you.

The meeting then closed.

DR. SIEMENS ON TECHNICAL EDUCATION.—The annual meeting for the distribution of prizes and certificates in connection with the Institute for the Advancement of Technical Education was held this week in the hall of the Goldsmiths' Company, Foster-lane. After the presentation of the prizes, Dr. Siemens said that Sir Frederick Bramwell had prevailed upon him to present the prizes on this occasion, and had urged that he was a fit person to do so. The distinction made between ordinary and honour prizes, marking the addition of some scientific knowledge to proficiency in applied science, was worth the attention of all students. It was not sufficient for after-life to be efficient in a craft or calling. Unless the workman also mastered entirely the scientific principles underlying that calling, he might, in consequence of some invention changing the *modus operandi* in an occupation, be left high and dry, whereas with a knowledge of fundamental principles he could adapt himself to changed circumstances.

GAS EXPLOSION.

About half-past four in the afternoon of Saturday last passers-by in the Strand, in the vicinity of Charing-cross Station, were startled by a loud explosion and crashing of glass. A large crowd gathered about the shop of Mr. John Chandler, who occupies one of the small box-like compartments between the gateways leading to the station, as a cigar shop. Gas was employed for both lighting and heating, and by some unknown cause a large amount had leaked from the pipe which is laid under the floor, and, the latter being covered with linoleum, a quantity of gas had accumulated. This being ignited by the gas jets above, a terrific explosion followed, tearing a large hole in the floor, blowing out the rear and inside front window glass, and scattering the goods about promiscuously. A large case was thrown into the yard outside, and two of the feet of the gas stove—which was not in use at the time—were carried by the force of the explosion into the railway station. The sole occupant of the shop at the time was a young man, who was behind the counter when the accident occurred, and narrowly escaped being killed. He was, however, only slightly scratched by the counter being thrown over on him. Had there been any customers in the shop at the time they must have, by reason of the smallness of the place, been standing immediately over the spot where the explosion occurred, and nothing short of a miracle could have saved them from being killed. Gas may be cheap, but it is sometimes nasty as well.

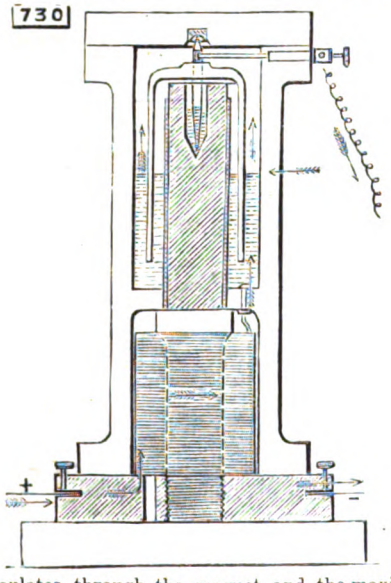
RECENT INVENTIONS.

ABSTRACT OF SPECIFICATIONS.

730. Improvements in Apparatus for Measuring and Registering Electric Currents, *C. A. Faure, Strand, London.*—15*th February*. 6*d*.

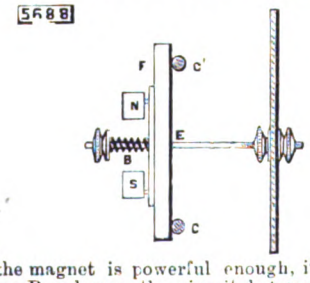
The principle of the invention is that a conductor conveying a current tends to rotate round a magnet. The apparatus is illustrated in the accompanying figure. A cylindrical electro-magnet is mounted vertically within a vessel containing mercury. A conductor in form like the flier of a spinning machine is pivoted on the top of the magnet core, and its arms dip down into the mercury. The current to be measured



circulates through the magnet and the moving conductor, and as the force required to move any object through a liquid is proportional to the square of the speed, it follows that the number of rotations of the conductor will be proportional to the current to be measured. The registering part of the apparatus may be independent of the above, and consists of an electro-magnet and armature similar to that of an electric bell, and arranged with a train of wheels. Each pulsation of the armature registers permanently.

5688. Improvements in Cymaphens or Apparatus for Transmitting Sound by Electricity, *C. F. Varley, Bexley Heath, and F. H. Varley, Mildmay-grove, Middlesex.*—27*th December*, 1881. 10*d*.

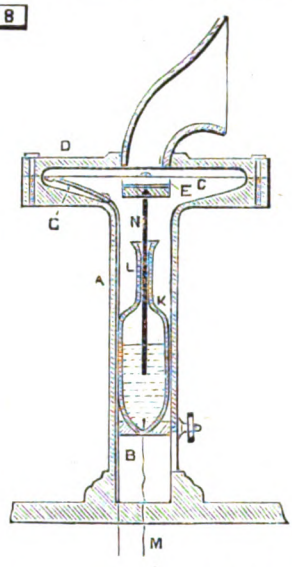
The figure shows one method of carrying out this invention. The style E projects through a carbon rod. On the end of E there is an adjusting nut for regulating the pressure spring B, which is made to press the carbon rod against the contact pieces C C¹. To the carbon rod an iron armature F is attached. Near F the poles N and S of an adjustable magnet are placed. These attract F and counteract spring B. Now,



if the magnet is powerful enough, it will overcome B and open the circuit between C and C¹. If the space between F and the poles N and S be increased the magnetic force is weakened, and spring B forces the carbon rod into contact with C and C¹. Thus, by regulating the resistance of N S and the force of B, any degree of contact pressure can be produced, and the most sensitive condition for transmitting sound by means of electric waves obtained. Many other methods of carrying out this invention are also described and illustrated.

688. Improvements in the Method of Transmitting or Reproducing and Repeating Sounds by Electricity, &c., *A. M. Clark, London.*—11*th February*, 1882.—(*A communication from G. M. Hopkins, Brooklyn, New York.*) 8*d*.

The first part of this invention consists in a contact surface attached to a vibratory diaphragm and a float-supported electrode pressed against the contact surface by a column of liquid. In the figure, E is a disc of carbon attached to the centre of the diaphragm C—metal or mica. If of metal, the diaphragm may be made part of the circuit by means of spring G. A glass bottle, K, is supported at any convenient height within A, as shown. A platinum wire, B, enters K, and is connected to wire M. K is partly filled with



mercury in contact with B, and which buoys up float-rod N carrying on its upper end a carbon disc. The float-rod is a conductor. This carbon disc is pressed by N into light contact with carbon disc E attached to C. Another part of the invention consists in two sets of electrodes insulated from each other and vibrated alternately in opposite directions, one set being placed in the primary telephonic circuit, and the other in the secondary, the object being to interrupt the secondary circuit so as to break up the effects of induction and render the induction currents and earth currents available in transmitting. Other improvements are described.

263,758. Process of Baking Carbon Rods, *Charles F. Brush, Cleveland, Ohio.*—*Filed May* 27*th*, 1881.

Claim.—(1) In the process of baking or calcining carbon rods or sticks, arranging the carbon rods or sticks in pyramidal form in a receptable and filling the interspaces and the spaces at the sides and ends of the pyramidal pile with suitable packing material, substantially as set forth. (2) In the process of baking or calcining carbon rods or sticks in a receptacle, arranging the carbon rods or sticks in pyramidal form on a slab or

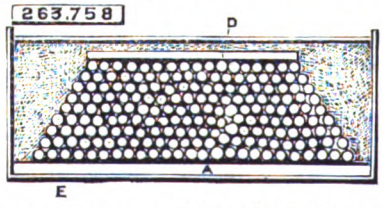


plate of suitable material to withstand warping, and filling the interspaces and the spaces at the sides and ends of the pyramidal pile with suitable packing, substantially as set forth. (3) In the process of baking or calcining carbon rods or sticks, arranging the carbon rods or sticks in pyramidal form on a slab or plate of suitable material to withstand warping, filling the interspaces and the spaces at the sides and ends of the pyramidal pile with suitable packing, and subjecting the pile to a superincumbent weight during the process of baking, substantially as and for the purpose set forth. (4) A pyramidal pile of carbons having the ends of its lower course formed of twin or connected carbons to prevent displacement, substantially as and for the purpose set forth. (5) The combination, with the pyramidal pile of carbon rods or sticks, of the supporting slab, the packing, and the enclosing box, substantially as and for the purpose set forth. (6) The combination, with the pyramidal pile of carbon rods or sticks packed in suitable material, of the supporting slab A, upper slab D, and enclosing the box E, substantially as and for the purposes set forth.

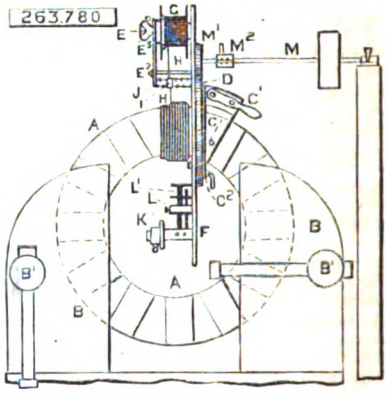
263,780. Machine for Winding Armatures for Magneto-electric Machines, *Robert Haase and John P. Recker, Indianopolis, Ind.*—*Filed August* 23*rd*, 1881.

Claim.—(1) The combination in a machine for winding wire upon annular armatures, of the divisable clamp C, constructed substantially as specified, and adapted to surround and be secured upon the rim thereof, and mechanism, substantially as described, secured to and adapted to revolve upon said clamps, substantially as and for the purposes set forth. (2) The combination, in a machine for winding wire upon annular armatures, of the surrounding clamp, the toothed rim, the arms thereon, the bobbin, a travelling guide, and an endless screw mechanism, substantially as and for the purposes set forth. (3) The combination, in a machine for winding armatures with wire in which one portion revolves upon another or stationary portion, of an endless screw or screws for driving a travelling guide, a star-shaped wheel upon the end of each screw, and projections upon the stationary part of the machine, with which said star wheel or wheels will come in contact as the revolving portion of



the machine moves past them, whereby said screws are revolved, the guide propelled, and the wire guided properly continually into place, substantially as set forth. (4) The combination, in a machine for winding annular armatures with wire, with the bobbin located upon one side of the centre of the revolving portion of said machine, of a weight L, upon the opposite side mounted upon a screw shaft L¹, having a star wheel L¹ upon its end, which comes in contact with points upon the stationary part of the machine as it revolves, whereby the position of the weight is continually varied to correspond to the decreasing weight of the wire, substantially as set forth. (5) The combination, in a winder adapted to revolve around the rim of an annular armature, of one arm carrying the bobbin for the wire and another arm upon the opposite side carrying adjustable counterbalancing weights, substantially as and for the purposes set forth. (6) The combination of the rim D, arm E, bobbin G, guide I, endless screws J J, having star wheels and stationary parts provided with projections, substantially as and for the purposes set forth.

2531. Improvements in Armatures for Dynamo or Magneto-electric Machines, *W. R. Lake, London.*—27*th May*, 1882.—(*A communication from J. J. Wood, Brooklyn, New York.*) 6*d*.

This relates to an improved method of securing the armature of the Gramme machine to its hub or shaft, and consists in the introduction at intervals of thin plates between the coil sections of the armature; these plates embrace iron cores and project into or are rivetted to the hub, thus producing a positive rotating connection between the armature and its hub, so as entirely to prevent the hub turning on the armature or slipping.

5400. Improvements in Electric Light Lamps or Lanterns, *T. Rowan, Coleshill-street, London.*—9*th December*, 1881. 2*d*.

This relates to a means for surrounding the light with prismatic lenses, so that it might be diffused around.

SLIP

GRAPHITE.—A vein of graphite has been struck at Coromandel, New Zealand.

ETHER.—Dr. O. J. Lodge was to lecture on this subject at the London Institution on Thursday night.

THE TELEPHONE IN NORTH AFRICA.—The Compagnie Générale des Téléphones of Paris is establishing exchanges in Algiers and Oran.

ELECTRIC LIGHTING AT DRESDEN (SAXONY).—The pianoforte manufactory of Herr Emil Ascherberg, in Dresden, is lighted by means of the Edison system.

ELECTRIC LIGHTING IN ABERDEEN.—The principal streets of Aberdeen were lighted for the first time on Saturday last by means of the Brush system of electric lighting. The experiment is to be conducted for a period of four months.

NOTES ON THE ELECTRIC LIGHTING ACT.—We have received a copy of a work on this subject from the authors, Messrs. Clement Higgins and G. W. W. Edwards. We shall hope to acquaint our readers with its style and contents before long.

WEST INDIES.—The cable between Antigua and Guadeloupe is interrupted; and as the cable between St. Vincent and Grenada is not yet repaired, there is at present no telegraphic communication with Guadeloupe, Dominica, Martinique, St. Lucia, St. Vincent, or Barbadoes.

THE EDISON SYSTEM IN BERLIN.—Ninety Edison lamps have recently been placed in the gas lanterns in Wilhelmstrasse, extending from the English Embassy to Prince Charles's palace. Each lantern has three lamps in it. The installation is, we believe, only experimental at present.

FIRE CAUSED BY ELECTRIC LIGHT WIRES.—It is stated that some cables leading to Brush lamps on Broadway, New York, recently came into contact with telegraph poles belonging to the Metropolitan Telephone and Telegraph Company, setting them on fire. No great damage was done, however.

THE FAURE COMPANY.—An interim dividend of 3s. per share has been declared by the directors of the Faure Electric Accumulator Company, payable on and after January 2, when the fully-paid shares in the proportion previously mentioned as to be given in exchange for the shares with £2 paid will also be delivered to applicants.

A HOLIDAY TASK.—We present our readers with a puzzle for New Year's Day. What German author defines magnetism thus? "Magnetism is centropheric antagonism, a radical line, $0, - — +$, the action of the line being cleft at one extremity. Magnetism has its root in the beginning of creation. It is prophesied with time."

THE TELEPHONE IN THE RIVER PLATE.—It is stated that arrangements have been made for the fusion of the interests on the River Plate of the Continental Telephone Company, of Boston, U.S., the purchaser of the rights, patents, and property of the Rio de la Plata Telephone Company and of the National Pan Telephone Company of Buenos Ayres.

NEW THEATRE AT CHESTER.—The new Royalty Theatre, to accommodate 2,000 persons, was to have been opened at Chester on Saturday night, but at the last moment it was discovered that the mechanical stage would not work, and several hundred persons had to be turned away. It is lighted by Brush lamps, which were tested and found to work satisfactorily.

ELECTRIC LIGHTING IN PARIS.—The proprietors of the Bon Marché in Paris have begun to replace gas in some of their departments by the Edison system. Five hundred Edison A lamps will replace as many gas burners in the basement and other parts of the building. It is stated that the telegraph office in the Rue de Grenelle is to be lighted by means of ten Cance arc lamps.

ELECTRIC LIGHTING FOR BIRKDALE (LANCS.).—The Southport Town Council have resolved that, in the event of the Birkdale Local Board proceeding with their application to the Board of Trade for a provisional order to supply Birkdale with electricity, the powers relating to the supply of that district contained in the order about to be applied for by the Southport Corporation be withdrawn.

THE TELEGRAPH AND TELEPHONE IN BRITISH GUIANA.—The *Colonies and India* says:—"On the introduction of a Bill to amend the present telegraph law, Mr. Russell said he feared its provisions would prevent the free introduction of telephonic communication, and the Government eventually consented to modifications to remove the presumed disability." The Bill was eventually read a third time and passed.

REMOVALS.—Edison's Indian and Colonial Electric Company have removed from their temporary offices at 6, Lombard-street, to Nos. 4 and 6, Throgmorton-avenue, Throgmorton-street, E.C.—The offices of the Gower-Bell Telephone, the Consolidated Telephone Construction and Maintenance, and the River Plate Telephone and Electric Light companies have been removed to the Telephone Works, Farringdon-road, E.C.

ELECTRICITY AND GAS AT AMSTERDAM.—We are informed that the Corporation of Amsterdam are in treaty for the purchase of the gasworks in that city, and that consequently they are looking with a somewhat cold and distant eye on matters electrical. Should, however, the present owners of the gasworks prove obdurate as to the purchase money to be paid by the Corporation, it is probable that the latter will warmly espouse electric lighting.

NEW COMPANY.—Articles of incorporation of the New York and Pennsylvania Telegraph and Telephone Company have been filed in the County Clerk's Office, New York. The new company is to construct, own, and maintain a line or lines of electric telegraph between New York and Erie, Penn., the principal cities on the route being Elmira and Binghampton. Its capital stock is now 50,000dols., divided into 500 shares of 100dols. each, but this may be increased to 1,000,000dols.

NEW SECONDARY BATTERY.—A secondary battery, invented by Messrs. Liardet and Donnithorne, has been on view at No. 38, Holborn-viaduct for some days. The main features of this battery are the intermixture of porous lead, deposited either by direct action by means of a galvanic current, or by the action of spelter, with oxides and salts of lead such as may be produced from galena or other lead ore. This mixture is placed on very thin plates of pure lead, and is kept in position by porous plates.

DEATH OF MR. C. V. WALKER.—Mr. C. V. Walker, F.R.S., past president of the Society of Telegraphic Engineers, and telegraphic engineer for the South Eastern Railway Company, died at Tunbridge Wells on Sunday, in the seventy-second year of his age. Mr. Walker was one of the oldest telegraphic engineers in the country, and was the inventor of several useful appliances, notably the instruments by which

Digitized by Google

the block system on railways is worked. We shall hope to give some further account of his life in a future issue.

PRESCRIBING BY TELEGRAPH.—A correspondent sends us the following:—"An *employé* of the Eastern Extension Telegraph Company, stationed at Cape Bolimao, Manila, had a narrow escape the other day, having taken 10 grains of sugar of lead in mistake for a similar quantity of ammonia. He telegraphed for advice to the Hong Kong telegraph office. Dr. Hartigan of that city came down to the office, and sent him advice per cable, which resulted in his recovery. The distance between Hong Kong and Cape Bolimao is about 555 miles." Probably this is the first time that a doctor has prescribed for a patient over 500 miles away from him.

TELEPHONING FROM LONDON TO BRIGHTON.—On Thursday last (Dec. 21), the London exchange of the United Telephone Company was experimentally connected with the company's exchange in West-street, Brighton, wires being carried there from the railway station. Ordinary post-office telegraph wires were utilised with satisfactory results, conversation being carried on between the two places, and voices recognised. Some induction noises were experienced, but not to any very great extent. Congratulatory messages were received and exchanged between the mayor and Mr. J. P Knight, the general manager of the Brighton Railway. Several leading townsmen and men of business also tested the telephone.

COUNTRY REPORTERS.—A lecture on lighting by incandescence was delivered a few days since by Professor Jones, at Firth College, Sheffield. The lecture hall was lighted by Brush lamps, and a few of Swan's, the arc lamps being supplied by the Yorkshire Brush Company. The lecturer, as reported by a Sheffield paper, was made to say in describing the Swan lamp, that "Between the carbons, in this lamp, is placed a piece of marble, which is rendered incandescent by the electricity from the carbons. The points of the carbons are pressed against the marble by springs, and while the current is passing through the marble a reddish hue is imparted to the light," &c. The reporter, however, is not so very much to blame, as the "Sun" lamp sounds very much like "Swan" lamp when spoken.

THE TELEPHONE IN BOSTON (AMERICA).—The Telephone Despatch Company of Boston, encouraged by the success of experiments made last year with a cable laid between two stations on the Old Colony Railroad, has obtained authority for laying subterranean lines in all the principal streets of that town, and is about laying cables of different kinds in the immediate neighbourhood of its central office. The cables are enclosed in iron tubes 100 millimetres in diameter (about 4in.), and embedded in cement; eight tubes are laid side by side in each trench. Some of the cables are formed of a simple wire, insulated by means of paraffin, and enclosed in a leaden tube, whilst others are composed of a certain number of wires insulated by india rubber, and protected by a covering of galvanised iron wire; they are laid in tubes, and can be changed as often as required.

TRANSMISSION OF POWER.—A Glasgow contemporary mentions the following application of electricity to the transmission of power. It appears that Mr. Joseph Atkinson was some few months ago engaged fitting zinc sheathing to the shell of the ss. "Snark" by the process for which he is the patentee, in the shipyard of Messrs. Denny, of Dumbarton. Using a Siemens D 7 generator, driven by an ordinary donkey engine, Mr. Atkinson transmitted through 150 yards of insulated wire a power equivalent to about six horses to a small motor near the vessel's side. This motor, manufactured by Messrs. Siemens, from designs supplied by Mr. Atkinson, was made to revolve at a high velocity, and drove a flexible shaft attached to which was an emery wheel. With this wheel the hard surface of the vessel's shell, which was of steel plates, was highly burnished at intervals of 9in., with spots about 2in. in diameter, to which the zinc sheathing was afterwards attached by solder.

THE TELEPHONE CASE.—The *Daily News* recently published the following paragraph:—"Last May, Mr. Justice Fry, in the case of the United Telephone Company (Limited) *v.* Harrison, Cox-Walker, and Co., held that the Edison transmitter patent was void. Against this decision the United Telephone Company appealed, and we are informed they have to-day withdrawn their appeal." In reply to which the chairman of the United Telephone Company wrote:—"As the paragraph with regard to the withdrawal by the United Telephone Company of their appeal from the decision of Mr. Justice Fry is liable to be misunderstood, I shall feel obliged if you will allow me, on behalf of the company, to explain the facts. Mr. Justice Fry's decision was in favour of the company on all points relating to the telephone, and was adverse only because the phonograph was contained in the same patent, the claim for that instrument being held by his lordship to be bad on a technical ground. The phonograph has since been struck out by disclaimer, and upon the patent as it now stands Mr. Justice Fry's decision is in favour of the company on all points. The company has, therefore, no reason for desiring to disturb the existing decision."

THE TELEPHONE.—On Sunday night last Mr. W. Lant Carpenter delivered in the Queen's Rooms, Glasgow, the fourth of the present series of lectures under the auspices of the Glasgow Sunday Society. Mr. Lant Carpenter, whose subject was "The Telephone, the Microphone, and the Photophone," gave an interesting account of these instruments, illustrating his description by experiments. In speaking of Mr. A. Graham Bell, to whom he ascribed the invention of the telephone, he said his audience would be proud to learn that that gentleman was a Scotchman, having been born in Edinburgh, where his father, Mr. Melville Bell, was an elocutionist. Mr. Melville Bell had been led to contrive a universal alphabet capable of expressing any sound, and had ultimately intimated that he thought that alphabet could be used to train deaf mutes to speak. Having been asked to go to America in order, if possible, to carry out his scheme, he sent his son, Mr. A. Graham Bell, instead, who accordingly went to that country and started a school for that object. In the course of his work the latter gentleman had invented an instrument which gave a graphic delineation of sound by light cast on a mirror, and this invention, after various changes, described in detail by the lecturer, terminated at length in the construction of the modern telephone.

ELECTRIC LIGHTING IN MINES.—Messrs. Bell Brothers successfully tried for the first time, on Wednesday evening, says the *Newcastle Chronicle* for Saturday last, the electric light for illuminating the works both above and below bank at their Page Bank or South Brancepeth Colliery. The system used is that of the Maxim Weston Electric Light Company, and there are nine lights at bank on the pit heap and in the engine-houses, and 24 underground, 17 of these being in the Brockwell Pit at the shaft bottom, sidings, stables, and engine-house. The other seven are in the Busty Pit, similarly placed to those in the Brockwell. These lights are driven by a double engine, with a pair of 10in. cylinders

Digitized by Google

with 20in. stroke, at a speed of 90 revolutions per minute, which gives 800 revolutions on the dynamo. This dynamo is capable of working 90 lights of 25 candle-power each. A second engine is in a forward state, and in the course of another week will be at work, when the whole of the surface works, colliery offices, managers' and engineers' houses, &c., will be illuminated with the electric light. The engines for working the dynamos are driven by steam, obtained from the waste heat of the coke ovens, which are close by. This enterprising firm are also engaged in making oil from condensed gases, drawn from the coal while burning in the ovens, and it is likely to be a commercial success.

Electric Lighting in Mills.—The agent of the Wamsutta Mills, writing to an American paper, gives the following figures with reference to the Edison system in use there:—"The plant cost about 12,000dols., and consists of three K dynamos, each of the capacity of 250 A lights of 16 candle-power each. One light serves four looms, giving an equal amount of light to each loom. In other parts of the mill the arrangement is such that one lamp lights about the same space as two four-foot gas burners. The whole system from the word go has moved along without a hitch. The agent says it is as cheap as gas at 1dol. per 1,000 feet, there is no smoke or heat from it, it is safer than gas, and it does not vitiate the air we live in. The dynamos are operated by one of the machinists, requiring but a small portion of his time. The power required is by actual test one horse-power for 8·6 lights of 16 candle-power each. The cost for power, taken in connection with the power to drive the mills, is very light, at the night end of the day. They are unable to detect any increase in the consumption of coal, but the fires are probably burned a little lower. The cost of lighting our mill, which contains 51,000 spindles and 1,072 40in. looms, putting the power at 30dols. per year per horse-power, is estimated as follows:—87 horse-power for 300 hours at 30dols., 261dols.; 375 lamps at 1dol. each, 375dols.; labour operating dynamos, 90dols.; interest and wear and tear on plant at 8 per cent., 960dols.; total cost of electric light, 1,685dols."

The Telephonic Administration of Oaths.—The administration of oaths by telephone is losing its novelty. On Dec. 4, in New York city, the Recorder so administered oaths to six physicians in a small-pox hospital, who were required to swear to the correctness of their accounts. "Have they all got their hands on the book?" asked the Recorder. "Yes, all ready," replied Dr. Hurd, the physician in charge. "Very well, then," said the Recorder, "you, as my deputy, repeat to the deponents what I say. You and each of you do solemnly swear ——." "You and each of you do solemnly swear ——" repeated Dr. Hurd. "That the annexed accounts are just, true, and unpaid ——" said the Recorder through the telephone. "That the annexed accounts are just, true, and unpaid," repeated the Doctor. "So help you, God!" said the Recorder through the telephone. "So help you, God!" repeated Dr. Hurd. "Now kiss the book," said the telephone. "Kiss the book," repeated the Doctor. The six hospital attachés kissed the Bible in turn. "They've all kissed it," said the Doctor, through the telephone. "They have!" answered the Recorder in surprise. "Why, I did'nt hear it. Let them kiss it again, loud enough for me to hear it." The kisses were repeated with an energy that sent the reports vibrating over the wire vigorously enough to be reproduced on the metallic disc at the receiving end. "I heard those. That's all right; good bye," said the Recorder, hanging up his ear-piece. An American contemporary remarks:—"Administering oaths by telephone is not a commendable practice, but if it is ever justifiable it is where one of the parties is in a small-pox hospital."

Electric Exhibition at the Westminster Aquarium.—We understand that this exhibition is shortly to be opened. For this purpose motive power to the amount of nearly 500 horse has been prepared by the direction of the Aquarium, and is being laid down in the buildings specially erected as machine annexes. The body of the hall of the Aquarium will be devoted to arc lighting, which will be represented by fourteen or fifteen systems, several of which are new. The space underneath the galleries and the galleries themselves have been sub-divided into courts for the purpose of exhibiting the several systems of incandescent lighting and fittings applicable to it. The ground floor of the whole of the building and parts of the galleries are apportioned out to exhibitors for the purpose of displaying the different applications of electricity, the most notable of which will be the motors, fourteen in all, which will drive machinery. The dining annexe will be lighted by Messrs. Ferranti, Thompson, and Ince with 350 incandescent lights, fed by one of their new dynamos. There is a series of five courts fitted up for the display of the Edison electric light and the different features of the Edison system. All the other courts are occupied by other firms to illustrate either new incandescent lamps or fittings for their use. The Metropolitan Brush Company have contracted to light up the Imperial Theatre during the course of the Exhibition, and we understand that their installation will be ready by the 6th January. Altogether the Exhibition promises to be of interest. From its situation it is very accessible for every one. We reserve further details for a future issue.

Dynamos.—The third lecture of the series on "Dynamo-Electric Machinery" was delivered at the Society of Arts on Monday week by Professor Silvanus P. Thompson, who took for his subject the dynamo as a motor. He said that efficiently to transmit power by electricity the generator and motor should be similar in construction in most respects. Uniform speed in the rotation of the armature of the generator was a desideratum, and gas engines which were driven by pulsations were not so desirable as other sources of power. Professor Ayrton had perfected a machine which was based on all the theoretical principles necessary for a machine to be self-adjusting whatever be the variation of work required from it; and it was his (Professor Thompson's) impression that a very near approach to perfection was arrived at in the combination employed in that instrument. In motors containing a single coil, such as the Griscom, Trouvé and Deprez, "dead" points were a great drawback. Boats had been propelled by electricity, and though Trouvé had abandoned the Planté secondary battery for the bichromate battery, the lecturer would not be more surprised to see large vessels propelled by electricity than those who saw the early beginning of steam would be if they awoke and saw how vessels were at the present day propelled by steam. Electric motors had only been used to a small extent to what they could be in places where steam or gas engines were undesirable or inadmissible, and the lecturer concluded by an expression of opinion that there was a greater future before electric motors than for electric lighting, and when a proper distribution of electricity through every town had been arranged, a far more potent agent would be possessed than was ever dreamt of, and people would then begin to realise how electricity could be utilised to meet their requirements. We shall give the first of this series of lectures with illustrations in an early issue.

The Electric Lighting Act.—As we predicted not very

Digitized by Google

long ago, more than one local authority, fearing the responsibilities and expenses of electric lighting, has withdrawn its application for a "provisional order" under the Electric Lighting Act. If these cases of withdrawal are cases where the applicants had applied for powers to supply electric light to the whole of the area within their jurisdiction, a very wise course has been taken. But it is material to point out that it is not obligatory upon a local authority, or even upon a company, to apply for or take powers having so wide a scope. On the contrary, there seems to be no limit to the smallness of the area within which the powers of the Act may be exercised, and the local authority may supply the light to one part of a town, and a company to the rest of a town, or the rest of the town may be apportioned to as many companies as the Board of Trade please, or be left unsupplied with the electric light. The words of the Act (Section 4) are that "The Board of Trade may, from time to time, by provisional order, authorise any local authority, company, or person to supply electricity for any public or private purpose, within any area;" and all that the Board of Trade Regulations require under this head is (Rule 4 of October, 1882), that the draft application must contain, among other things, "a description of the proposed area of supply." When the area is allotted, and the order granted, the severe provisions of the Act as to compulsory supply and so forth may (or may not if the Board of Trade so please) be brought into force, and it is natural to expect that these provisions would be put in force in proportion to the size of the area. But it is obvious that an experiment could be better tried with a small and much-frequented area than a large one, and that such an area would, in many cases, need the light more than all the other streets of a town. We doubt whether withdrawing applicants would have power to recall their withdrawal, but if they should be unable to do so, perhaps recourse may be had to that provision of the Public Health Act, 1875 (Section 161), which enables an urban authority to contract with any person for the supply of "gas or other means of lighting" the streets—which "other means" must include the electric light—and so the local authority may be enabled to dispense with Board of Trade licences or provisional orders altogether. —*Solicitors' Journal.*

THE TELEPHONE IN NEW YORK.—We extract the following from an article under this head in a recent issue of *The Operator*:—"The Metropolitan Telephone and Telegraph Company confines itself to providing telephonic communication to subscribers, and to the construction, leasing, and maintenance of private lines in the city. On the latter, telephones, Morse, or printing instruments are used, as the lessees may prefer. They are not connected with the exchanges. The number of subscribers connected with the exchanges is at present about 3,000. The advantages of the telephone service to business men are shown by the facts that, while new applications for telephones come in at the rate of about 70 per month, the number of those who withdraw does not exceed five or six in the same period. Complaints of failures in the service are infrequent. The rental charged is 150dols. a year. This covers the entire service. The rate is uniform throughout the city. The company has nine exchanges distributed throughout the city. Subscribers' lines, as stated above, terminate at the nearest exchange, and the exchanges are connected by 270 'trunk' lines. All the lines are of No. 12 galvanised iron wire. A number of aërial cables span various parts of the city, the longest extending from Murray-street to Twenty-first-street, a distance of over two miles. Others are on Broadway, and several cross the Suspension Bridge to Brooklyn. Subaqueous cables in the North River unite New York and Jersey City; others are laid beneath the Harlem River. All of these are kerite cables, some having each conductor encased in tinfoil, while in others each separate conductor has, outside of the kerite covering, a thin coating of plumbago. These devices are found effective in suppressing inductive disturbances. With the exception of a manager and three switchmen in each exchange, the *employés* of the exchanges are all girls. In all, about 140 operators are employed, and 19 linemen keep the lines clear. Blake transmitters and Bell receivers are usually furnished to subscribers. Those who prefer Edison's instruments are furnished with them. The conversations between subscribers average 17,000 per day. The present, on account of its being the holiday season, is the busiest time of the year in the exchanges, which just now present scenes of remarkable activity. One Leclanché cell is usually furnished to subscribers; on long lines, frequently used, two Callaud cells are substituted. All cells are inspected and cleaned once a week by battery men, sent out by the company in waggons, except in the thickly-crowded districts, where they go on foot. In addition to the subscribers' lines the company has 29 lines which terminate in offices of the American District Telegraph Company, in various parts of the city, for the use of the general public. For five minutes' conversation with any subscriber in New York or Brooklyn a toll of 20 cents is charged; 25 cents to Jersey City, Newark, &c.; 30 cents to Elizabeth, Yonkers, &c.; and 35 cents to Plainfield, Sing Sing, &c. The system of the Law Telegraph Company extends over New York city and Brooklyn. This company uses the same instruments as the Metropolitan Company, and confines itself to telephony. It has 600 subscribers. The number of subscribers being limited by the terms of the company's license, no additions are made to this number. It has two exchanges in New York and one in Brooklyn. The rental to subscribers located within half a mile of an exchange is 15 dollars per month; to others from 15 dollars to 25 dollars per month, according to their distance from an exchange. This rental covers the entire service, including the lease and maintenance of the subscribers' lines. The lines are constructed of No. 11 galvanised iron wire. Some twenty-five 'trunk' lines connect the company's exchanges with each other, and about forty-five similar lines connect the exchanges with those of the Metropolitan Company. About two-thirds of the subscribers are members of the Produce Exchange, and the remainder are nearly all attorneys. The exchanges are only open from 8 a.m. until 6 p.m. Each subscriber has an exclusive wire. The company uses no cables. So compact and simple is the Law exchange system that five operators in each of the New York exchanges, and one in the Brooklyn exchange, are able to serve all the subscribers, although a record kept for the last three days of last August, at the request of the Committee on Statistics of the National Telephone Association showed the number of conversations between subscribers to average 6,000 a day. The system is rapidly coming into use in other cities. It is now used in Philadelphia, by the Bell Telephone Company of Philadelphia, which recently set up four Law tables, for 500 wires each. The Bell Telephone Company of Missouri uses the system in its St. Louis exchanges, where it has four Law tables for 400 wires each. It is also used by the Missouri and Kansas Telephone Company in its Kansas City exchange, and by the Southern Bell Telephone Company in various cities in the South, among which are Richmond, Charleston, Atlanta, Mobile, Montgomery, Savanah, and Columbus G."

DRAFT PROVISIONAL ORDERS.

The Electric Lighting Act of last Session authorises the Board of Trade from time to time to grant *licenses* to local authorities, companies, or persons for the supply of electricity over a certain area under certain conditions. The Board of Trade may also from time to time authorise by a *provisional order* any local authority, company, or person to supply electricity over a certain area under certain conditions.

The applicant for a license must have the consent of the local authority having jurisdiction over the district for which a license is sought. The license expires at the end of *seven* years, but may be renewed.

The applicant for a *provisional order* must give notice to the local authorities of his intention to apply for such order, and the order is of no force until it is *confirmed by Act of Parliament*. The time during which a provisional order is in force seems to be unlimited, but provision is made by which the local authority may purchase at the expiration of twenty-one years—or earlier by agreement—and the powers then vest in the local authority.

The Act in Section 6 provides that:—

The undertakers shall be subject to such regulations and conditions as may be inserted in any license, order, or special Act affecting their undertaking with regard to the following matters:—

(*a*) The limits within which, and the conditions under which, a supply of electricity is to be compulsory or permissive.

(*b*) The securing a regular and efficient supply of electricity.

(*c*) The securing the safety of the public from personal injury, or from fire or otherwise.

(*d*) The limitation of the prices to be charged in respect of the supply of electricity.

(*e*) The authorising inspection and inquiry from time to time by the Board of Trade and the local authority.

(*f*) The enforcement of the due performance of the duties of the undertakers in relation to the supply of electricity by the imposition of penalties or otherwise, and the revocation of the license, order, or special Act where the undertakers have, in the opinion of the Board of Trade, practically failed to carry the powers granted to them into effect within a reasonable time, or discontinued the exercise of such powers; and

(*g*) Generally with regard to any other matters in connection with the undertakings.

Provided always that the Board of Trade may, from time to time, make such regulations as they may think expedient for securing the safety of the public from personal injury, or from fire or otherwise, and may from time to time amend or repeal any regulations which may be contained in any such license, order, or special Act in relation thereto; and any regulations so made or amended by the Board of Trade shall, from and after the date thereof, have the like effect in every respect as though they had been originally inserted in the license, order, or special Act, authorising the undertaking, and every regulation so repealed shall, from and after the date thereof, be repealed accordingly, but such repeal shall not affect any liability or penalty incurred in respect thereof prior to the date of such repeal, or any proceeding or remedy which might have been had in relation thereto. . . .

It will thus be seen that the rules of the Board of Trade have to be complied with to obtain a provisional order. These rules require proof of consent of local authority to application for a *license*.

They state that preference is given to applications from local authorities. They require publicity to be given to the application by advertisement, &c. Certain formalities must be gone through before certain specific dates. The draft order as proposed by the applicants must contain, among other things, information relating to area of supply, purposes of supply, description of the proposed works, the breaking up of streets, conditions of supply, cost, nature and amount of supply, obligation to supply, period of concession, safety of public and consumer personally and from fire, &c., provisions for enforcement of duties, &c. Various papers have to be lodged, and so on.

We may consider the Act and the Board of Trade rules as generalities, and the provisional order as the special and important work. The work, in fact, under which more directly the production and distribution of electricity is to be carried on. The provisional order sanctioned by Act of Parliament is as much law as the Lighting Act itself. The Electric Lighting Act is an entirely new departure. It authorises the distribution of "energy" for the first time in contradistinction to matter. The provisional orders, as allowed by Act of Parliament, next Session will be models for future draftsmen to use, and, therefore, it is extremely important that the "model" should be as perfect as possible. We have before us a "draft provisional order" similar to those lodged in accordance with the Board of Trade rules. This order has been drafted by one of the ablest lawyers, who at the same time is well versed in scientific matters, and who has given special attention to the developments of electricity. The draft shows that an immense amount of pains has been taken to fulfil the conditions determined by the Act and by the rules of the Board of Trade. The interests of the public no less than the interests of the applicants have been considered, and so far as we can at present judge the draft order seems to be complete and little open to unfavourable criticism. We shall now briefly abstract the order, giving the salient points in full, so that any reader may be able to criticise fairly, and we are sure that genuine criticism will be thankfully received by all who are interested in electric lighting. The order commences with formal clauses giving title, address of applicants, and description of area it is proposed to supply. It then proceeds to consider the general powers to be observed to enable the undertakers to manufacture, repair, let on hire, sell, supply, erect, maintain the apparatus, to make contracts, to take up streets and lay down wires, to erect the works, and so on. The primary object of the supply of electricity is for lighting purposes, but the undertakers "may supply electricity for all public and private purposes."

The nature and mode of supply is described under the following systems:—

(*a*) The *Direct System*, which is the name adopted for the simple "multiple arc" system. The conductors leading from the mains to the consumer's premises are called *service lines*, and the portions of such mains which are used for the purpose of giving origin to the service lines are called *distributing mains*.

(*b*) The *Storage System*, that is utilising reservoirs or storage batteries placed on the premises and under the control of the undertakers. The mains used for charging these storage batteries are called *charging mains*.

(*c*) The above but with earth returns.

(*d*) The *Series System*. In this system, as is well understood by electricians, the lamps are in succession in the same circuit. The consumers have not, as in the direct system, separate and independent circuits, but are dependent on the one circuit.

In addition to the above, any other system of distribution can, by agreement, be used. The undertakers supply to two poles or terminals upon the consumer's premises, past which terminals their liability does not extend. An important section makes optional the use of distributing and testing boxes. These are boxes placed at intervals in connection with the mains, and from these boxes the service lines are taken, and from these boxes, mains, service lines, charging lines, &c., can be tested, and connections made or broken, &c. The use of such boxes obviates the necessity of breaking up the streets, or breaking into the main conductor in order to connect house or branch lines.

The undertakers *shall* lay down, maintain, &c., suitable distributing mains in certain specified streets (these streets are named in Schedule A), also *shall* (if required by local authorities) arrange for the public lighting of specified streets either by the incandescent or arc system, at a price to be agreed upon or settled by arbitration. In addition, the undertakers *may* lay down and maintain, &c., distributing

Digitized by Google

mains in streets, &c., in area specified. If the work is not done in three years the Board of Trade may call upon the undertaker to carry out the work in the optional districts, provided the work can be done at a reasonable profit. A provision is made so that the Board of Trade can, if it sees fit, strike out the names of any streets, &c., they consider it advisable not to retain. The time during which the supply is to be guaranteed will, of course, differ in different districts. This has to be stated in the order, but is obviously a matter of detail and not of principle. The supply has again to be distributed at a standard difference of potential, which again differs according to the system adopted and the conditions in vogue. The standard may be different for different points in the mains, and for different hours during the period of supply. A variation of 10 per cent. is the limit of variation for the difference of potential. The resistances of the service lines are to be such that they will not cause more than 2·5 per cent. difference of potential between the consumer's terminals. The case of "alternate currents" is provided for, as is time for testing. The owners of premises within *fifty feet* of a distributing main can demand a supply of electricity—this demand does not hold with regard to a *charging main*. The consumer has to state the maximum current he requires, and the undertakers can refuse to supply a greater maximum than can "reasonably be required." If the maximum exceeds *fifty amperes* the same will be given off at more than one set of terminals, so that the maximum current at any pair of terminals shall not exceed "fifty amperes." Before referring to the conditions as to price, it may be said that generally meters of approved construction are to be used, and that these meters are to be under the control of the undertakers. It is extremely interesting to have a definite reply to a questioner who asks, How will the companies charge for the current? In the draft before us, Section 34 and Schedule C deal fully with this. The section states that the undertakers may elect to charge by one or other of five systems, or otherwise by agreement. The schedule gives the unit and the maximum amount that can be charged. The systems are—

(1) By the quantity of energy contained in the supply.

(2) By the actual quantity of electricity so supplied.

(3) By the number of hours during which the supply of electricity is actually used by the consumer and the maximum current required to be supplied.

(4) By a yearly or other rental, depending upon the maximum current required to be supplied.

(5) By a charge which is calculated partly by the quantity of energy contained in the supply and partly by a yearly or other rental depending upon the maximum current required to be supplied.

It may, perhaps, conduce to clearness if we now give

Schedule C.

The term unit, as used in this schedule, shall be deemed to mean the energy contained in a current of one thousand amperes flowing under an electromotive force of one volt during one hour.

Section I.—In case the undertakers shall elect to charge any consumer by the quantity of energy contained in the supply given to him, they shall be entitled to charge him at the following rates per quarter of a year:—For any quantity up to one hundred units, three pounds fifteen shillings, and for each unit over one hundred units ninepence per unit.

Section II.—In case the undertakers shall elect to charge any consumer by the actual quantity of electricity supplied to him, they shall be entitled to charge him according to the rates set forth in Section 2 of this schedule; the quantity of energy contained in the supply given to him being taken to be the product of the actual quantity of electricity supplied to him and the standard pressure at the point of junction of the mains and the service lines by which he is supplied.

Section III.—In case the undertakers shall elect to charge the consumer by the number of hours during which he shall actually use his supply, they shall be entitled to charge him at the rates specified in Section 2 of this schedule; the quantity of electricity supplied to him being calculated on the supposition that the consumer uses the maximum current specified by him under the provisions of Section 27 during all the hours that he has used the supply.

Section IV.—In case the undertakers shall elect to charge the consumer a sum by way of yearly or other rental, they shall be entitled to charge him the rates specified in Section 3 of this schedule; the number of hours during which he has taken the supply being taken to be *three-fourths* of the number of hours during which the supply was continued during the period to which such rental relates.

Section V.—In case the undertakers shall elect to charge the consumer by the method set forth in Section 34, Subsection (5), they shall be entitled to charge as follows:—At the rate of thirty shillings per annum for every ampere in the maximum current, in case the supply is given at a standard pressure of not more than 100 volts, and at a price higher in proportion to the standard pressure in case such pressure is more than 100 volts, and in addition thereto a charge of sevenpence-halfpenny for every unit actually used.

It is somewhat out of our province to discuss the pains and penalties clauses, suffice it to say that consumer and undertaker can be punished for wrong-doing—for omissions or commissions. The regulations as to safety, &c., contained in this draft order state—

(*a*) That the maximum current for distributing or service lines is 2,000 amperes per square inch of section of pure copper wire of equal conductivity.

(*b*) That leakage must not exceed 10 amperes per mile run.

(*c*) That the lines shall be waterproof, and protected from injury.

(*d*) That the circuit may be broken at some point outside the premises.

(*e*) That fusible safety plugs shall be used, so that the circuit is broken when a current 100 per cent. (or less, as seems fit to undertakers) over the maximum current the line is intended for goes through it.

(*f*) The terminals to be of an approved pattern, and not less than 3in. apart.

(*g*) When earth returns are used the earth contact to be good.

(*h*) Difference of potential at corresponding points of distributing or service mains not to exceed 300 volts.

(*i*) Difference of potential of charging mains not to exceed 4,000 volts.

Or as agreed upon and approved by Board of Trade for arc lighting.

Within buildings:—

(*a*) The conductors are to be such that the maximum current at any time shall not exceed 2,000 amperes per square inch of section of a pure copper wire of equal conductivity.

(*b*) No part of conductor to be naked and unprotected.

(*c*) Conductors laid within *six* inches of walls, &c., to be insulated with a covering giving a minimum insulation for whole building of not less than 5,000 ohms per volt in the standard pressure at the junction of mains and service lines. The covering to be waterproof, and have an external fireproof covering.

(*d*) Apparatus to be insulated.

(*e*) Conductors (except at terminals) to be not less than *one* inch apart.

(*f*) Resistance of circuit not to be below a certain specified point.

(*g*) No part of circuit to be put to earth.

(*h*) If earth returns used, no part of circuit to be put to earth except through pole of earth return.

It will, we think, be admitted that the draft order, with parts of which we have thus briefly dealt, is worthy of careful consideration, and is no mean achievement of the draftsman.

Electric Lighting in Charleston (America).—The United States Electric Light Company began lighting the streets of Charleston, S. C., Dec. 5. The company now have 36 arc lights for street lighting, and 15 in the Agricultural Hall Building, and 107 incandescent lamps also in the Hall.—*Sanitary Engineer* (New York).

MAGNETIC FORCE AND CURRENT.—III.

BY OLIVER HEAVISIDE.

In the previous articles under the above title (pp. 6 and 32) we explained the nature of two operations of frequent occurrence in electro-magnetism, viz., from a given vector-function to derive its "curl," and also to find its vector-potential; and some of the relations of these functions were mentioned. But that was for descriptive purposes merely; the only proof that curling the magnetic force gave rise to the current was that derived from the known magnetic force of a straight current, together with the assumption of a certain distribution of force within the current itself. [It was stated, by a slip, that the magnetic force within the current was "known" to be so-and-so, as if it could be measured at the spot, like the external force.]

We have now, to make the matter a little more complete, to prove that the properties ascribed to the vector-potential of current and its curl are really true, and to further develop them. It need not be thought that a knowledge of mathematical analysis of a high order is required, for it so happens that nearly the whole of investigations in electro-magnetism (although they may be of a very involved nature, the causes whereof were briefly alluded to on p. 55) are, when resolved into their simplest forms, merely the application in various shapes of the three theorems given on pp. 55-7; and these theorems are of such a nature that they may be reasoned out mentally, without symbolical aid save for final expression; and, in fact, in thinking them out in this way we may obtain a far clearer conception of what the theorems really mean than by working them out analytically, blindfolding the mind, so to speak, and working mechanically. No disparagement is intended of strictly symbolical demonstrations, or of the labours of the great mathematical electricians. To use a simile which may be readily applied, when once a bold explorer has reached the top of a hitherto inaccessible mountain, by circuitous paths and with the expenditure of great labour, others can do it after him, and easier routes may be discovered; and in course of time people may travel up comfortably seated in railway carriages. And, of course, it is still easier to start from the top and travel down. (A fall down a precipice, in seeking a short cut, may be compared to an abrupt breach of continuity in the reasoning.) A sound knowledge of the fundamental *principles* of the Calculus is desirable, but, so far as general results go, apart from special, very little of the *practice* thereof, for differentiations and integrations are usually merely indicated, not performed.

We have, in the first place, to clearly conceive what is meant by a flux of no convergence, and this is best done by means of a material analogy. Think of a frictionless, incompressible fluid filling all space. Within a given volume there must be always the same amount of fluid. If, then, we suppose the volume fixed in space and the fluid to be in motion, the same amount of fluid as enters it through its surface at some places must leave it at others, in any given time; or, algebraically, the total flux through the closed surface from within outwards must be *nil*. This is self-evidently true for any closed surface anywhere situated, and however the fluid may be moving. The flux through the surface of the element of volume is $= \frac{dX}{dx} + \frac{dY}{dy} + \frac{dZ}{dz} \times$ volume per second, if X, Y, Z are the component velocities in the directions x, y, z (Theorem I., p. 56), consequently $\frac{dX}{dx} + \frac{dY}{dy} + \frac{dZ}{dz} = 0$ in the case of an incompressible fluid.

If we have any vector or directed quantity, R, components X, Y, Z, and we say that $\frac{dX}{dx} + \frac{dY}{dy} + \frac{dZ}{dz} = 0$, or that it has no convergence, we simply imply that the distribution of R is similar to that of velocity in a possible case of motion of an incompressible fluid, so that we may, without going wrong, guide ourselves by the material analogue.

We may represent the fluid motion by means of lines, their direction showing that of the motion, their density the velocity. Or, rather, this is a convenient method of imagining the motion, because, if we draw the lines on a sheet of paper, we can only strictly represent in this way the nature of the motion in a section of the fluid bounded by two close parallel planes, and we may require a different diagram for another part of the fluid. We may, indeed, represent on paper the distribution in three dimensions according to Maxwell's system, but this has the disadvantage of requiring interpretation, for in many cases it makes the lines densest where they (in a plane section) would be furthest apart. Similarly, we may employ lines to indicate the distribution through space of any vector magnitude, R. When there is no convergence anywhere the lines form closed curves. We may, indeed, imagine lines of force to go out to infinity, and so get lost sight of. Thus we may imagine an indefinitely long, straight current coming from $-\infty$ and going to $+\infty$, and the corresponding lines of vector-potential will behave similarly. But this is not realisable. However long the straight portion of the current may be, it must ultimately return to the starting point, when the lines of flow will form closed curves; and, at the same time, the lines of vector-potential will also do so.

We have next to consider vectors that have convergence. In an incompressible fluid this would imply that at a place of convergence more fluid arrived than left in a given time, or *vice versâ*, and that would mean that fluid was perpetually going out of or coming into existence at the place—an annihilation or creation of fluid. Places of convergence are, therefore, sources or sinks. In a field of electric force, *e.g.*, that between two charges $+e$ and $-e$ on insulated conductors, the lines of force start from the surface of one and terminate on that of the other. They do not form closed curves. In the dielectric between the conductors, the force has no convergence. Imagine any closed surface entirely in the dielectric, every line of force which enters the enclosed space leaves it again. Such a line is the representative of a tube of force, across every section of which the same amount of force passes. But if the closed surface be partly within and partly without one of the conductors, say the +, a certain number of lines of force leave it on one side and *none* enter it upon the other side; there is, therefore, negative convergence, and similarly at the − conductor there is + convergence. The amount of convergence per unit of surface is a measure of the negative electrification. In any vector-system R, the quantity $-\left(\frac{dX}{dx} + \frac{dY}{dy} + \frac{dZ}{dz}\right)$ is a measure of the convergence at any place, expressed for a unit volume.

[The corresponding expression for unit of surface is $(R_1 \cos \epsilon_1 + R_2 \cos \epsilon_2)$, where R_1 and R_2 are the values of R on opposite sides of the surface, and ϵ_1, ϵ_2 the angles R_1 and R_2 make with the normals drawn *to* the surface from opposite sides. $R_1 \cos \epsilon_1$ is the amount of R reaching the unit of surface from one side, and $R_2 \cos \epsilon_2$ from the other side. In the case of no convergence these quantities are numerically equal, but of opposite signs, so that $R_1 \cos \epsilon_1 + R_2 \cos \epsilon_2 = 0$; corresponding to $\frac{dX}{dx} + \frac{dY}{dy} + \frac{dZ}{dz} = 0$.]

To further illustrate the distinction between converging and non-converging vectors, consider a linear current with its ends immersed in a conducting medium. The lines of flow in the medium from the + to the − end are exactly similar to the lines of force between the two charges $+e$ and $-e$ before considered, so that if we were to ignore the linear current there would be + convergence at the place where the current enters the wire and − at the other end. Similarly, if we ignored the current in the medium, we should have convergence at the ends of the wire of opposite sign to the last. But, considering the complete system, there is no convergence anywhere, the above convergences cancelling. In the static electrical case there is no channel joining the conductors to make a complete circuit for the force, so there is really convergence.

It will be convenient, preliminarily, to alter the definition

Digitized by Google

of potential. Instead of the potential of any agent e at distance r being $\frac{e}{r}$, let it be $\frac{e}{4\pi r}$. If e is a scalar, so is its potential; if a vector, its potential is also a vector, to be drawn parallel to direction of e. In the case of electric force, this definition of potential implies that the force at distance r is of strength $\frac{e}{4\pi r^2}$, so that the whole amount of force leaving e is numerically equal to e. Now, the whole amount of force leaving any space is independent of the distribution of the free electricity within it (p. 55), and is numerically expressed by the amount of the latter. Expressed for a unit-volume, we now have (Theorem I., p. 56)

$$\frac{dX}{dx} + \frac{dY}{dy} + \frac{dZ}{dz} = \rho \quad . \quad . \quad . \quad . \quad (1),$$

ρ being the volume-density, so that $-\rho$ measures the convergence.

We shall now prove an important property of converging vectors having no curl. Let a vector be denoted by R, and suppose it is given in direction and magnitude throughout all space. Measure its convergence everywhere; *i.e.*, divide all space into elements of volume, find the excess of the amount of R, leaving any one of them over that entering it, and denote it by ρ per unit volume. Then we have Equation (1) again, where, however, ρ does not now mean the density of free electricity, but merely the convergence (with sign reversed) of the vector R. ρ is then known everywhere, being 0 at those places where there is no convergence. Next, let R have no *curl* anywhere. The line-integral of R once round any closed curve is then $= 0$, by Theorem II., p. 56; therefore, the integral of R from any one point A to any other Z is the same by any path, being determined solely by the position of A and Z; therefore, by Theorem III., the integral of R from A to Z $= P_A - P_Z$, where P is a scalar function of position, and the component of R in any direction s is $-\frac{dP}{ds}$. The direction of the resultant R is that in which P decreases fastest, and its magnitude is the rate of decrease. We may denote the resultant vector by $-\nabla P = R$, with components $-\frac{dP}{dx}, -\frac{dP}{dy}, -\frac{dP}{dz}$ in the three rectangular directions x, y, z.

The question now arises, how is the quantity P to be determined, starting with ρ given, and that R has no curl; *i.e.*, what is the explicit relation of P to ρ? If we consider a single element of volume, a unit cube for example, taking the unit indefinitely small, ρ is the excess of the amount of R, leaving it over that which enters. Now, disregarding altogether the manner in which R really enters and leaves the pace, let the quantity ρ give rise to a vector R′ in the same manner as free electricity gives rise to electric force, *i.e.*, let $R' = \frac{\rho}{4\pi r^2}$ at distance r from ρ, and be directed along r from ρ outwards, so that the whole amount of R′ leaving ρ is numerically $= \rho$. Let the same thing take place wherever there is convergence, and then find the resultant, *i.e.*, the vector-sum of $\frac{\rho}{4\pi r^2}$ or $R' = v.\Sigma\frac{\rho}{4\pi r^2}$ This new vector R′ obviously satisfies the condition expressed by Equation (1) above; by the manner of its construction the convergence anywhere is $-\rho$, for those of the lines of R′ which proceed from centres lying *outside* any one of the elements of volume which enter the latter leave it again.

Now, $\frac{\rho}{4\pi r^2} = -\frac{d}{dr}\frac{\rho}{4\pi r}$; *i.e.*, the flux from the element ρ is derived from the potential $\frac{\rho}{4\pi r}$, for the latter plainly decreases fastest along r outwards, and its rate of decrease is the strength of the assumed flux. Form next the sum of the potentials as above for all the elements, or $\Sigma\frac{\rho}{4\pi r}$ and call it P; then since

$$-\nabla\Sigma\frac{\rho}{4\pi r} = -v.\Sigma\frac{d}{dr}\frac{\rho}{4\pi r} = v.\Sigma\frac{\rho}{4\pi r^2},$$

therefore $R' = -\nabla P$.

We have thus found a scalar potential whose variation in space is a vector R′ which has the same convergence as R, and we may now easily prove that R′, like R, has no curl. For, by the general equations (Theorem II, p. 56) connecting a vector and its curl, the x-component of the curl of R′ is

$$\frac{dZ'}{dy} - \frac{dY'}{dz} = \frac{d}{dy}\left(-\frac{dP}{dz}\right) - \frac{d}{dz}\left(-\frac{dP}{dy}\right) = 0 \text{ identically,}$$

and similarly for the y and z components.

Now, is it possible for R′ to differ from R? If they do differ, let R″ be the difference. It must have *no* convergence, because R and R′ have the *same* convergence. But if R″ had convergence, some of the lines of R″ would terminate at certain places; therefore, having none, the lines of R″ must be closed curves. But if we integrate R″ once round one of these closed curves, we obtain a finite quantity, because the direction of R″ at any place coincides with that of the curve. But R and R′ have no curl, hence their difference R″ has none, consequently the line-integral of R″ round *any* closed curve is *nil*. Thus the lines of R″ cannot be closed, and since also they cannot terminate anywhere, it follows that they do not exist. Therefore, R″ is non-existent, and R′ = R identically. That is,

$$R = v.\Sigma\frac{\rho}{4\pi r^2} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (2)$$

is the complete solution of (1), with the condition that R has no curl.

Now, if in (1) we put for X, Y, Z their values in terms of P, viz., $-\frac{dP}{dx}, -\frac{dP}{dy}, -\frac{dP}{dz}$, we obtain

$$\frac{d^2P}{dx^2} + \frac{d^2P}{dy^2} + \frac{d^2P}{dz^2} = -\rho \quad . \quad . \quad . \quad . \quad . \quad (3)$$

Therefore, we have also found a solution of this last equation, viz.;—

$$P = \Sigma\frac{\rho}{4\pi r} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (4)$$

It may be shown that any other solution of (3) can only differ from this one by a constant quantity. For if there be another solution, say P + P′, then $-\nabla P'$ must have no convergence anywhere, because the convergence is fully given by that of $-\nabla P$ or R; and it must have no curl anywhere, because like R it is derived from a scalar potential; therefore, by the same reasoning as that proving that R″ was non-existent, we see that $-\nabla P'$ is non-existent, and hence P′ must be constant everywhere. This constant allows us to locate the zero of P where we like, it is most convenient to put P′ = 0, so that P = 0 at an infinite distance from places where ρ exists, and then (4) is the complete solution of (3).

A GUIDE TO PRACTICE IN THE SUBMARINE CABLE TESTING ROOM.

XI.

It is necessary to call attention to a point in connection with the use of the short circuit key referred to in the last number of this series, and in so doing we desire to impress on the learner the importance of taking at the outset a correct view in relation to detail. What some persons call "little things" or "trifles" not worth troubling about should have no place in his estimation. As a grain of sand might disturb the working of a complicated machine, or even cause its destruction, so the neglect of some apparent trifle in the course of a testing operation will prevent the attainment of a correct result. One of these "little matters" is concerned in the condition of the contact pieces in testing keys, and any instrument in which a circuit is continued by the contact of two little platinum pips. This metal is employed for the purpose, chiefly because it is less heated by the passage of a current than other metals; the points are thus kept cleaner, and freer from oxide than if they were of inferior conducting quality. When the short circuit arrangement just mentioned is employed, care should be taken that all these points are perfectly clean and fit well, that is, that the upper and lower contacts should accurately meet and touch each other firmly when caused to do so. In Fig. 21 (No. X.) the contacts of the short circuit piece are placed one on the under side of the bar, and the other on the upper side of the key piece. If these are not quite clean, if any dust settles on either, perfect contact is not effected, and the galvanometer is not properly protected in case of a current passing in the circuit. If a current passes while the galvanometer is supposed to be short circuited, there ought to be no deflection on the scale until the key is depressed. But if the caution is not observed a deflection will appear, though the short circuit is open, and the learner would certainly be in a difficulty if he did not know the true cause. It would be awkward if this happened with a cable connected up in circuit, for it would be charged, and the test could not be properly taken under the circumstances. The only safe course would be to take off the battery (free the battery key) and put the cable to earth for a time, postponing the test till it were thoroughly discharged.

In the course of our remarks on the "constant" we stated that the current passing in a circuit, and consequently the deflection given by the galvanometer through which it goes, is larger or smaller as the resistance in circuit is smaller or larger, so that, of two resistances, the larger would give a smaller deflection than the other. Now, we have shown that the deflections when testing cables for insulation resistance are larger when a long cable is in question than when a shorter one is observed. These two statements may, and most likely will, appear to the learner to be contradictory; but, if he has understood the remarks in which we compared the relation between the resistance per knot and the total or absolute resistance as regards conduction and insulation, he will not long feel doubtful as to the facts. It is evident, as observed in No. IX., that the longer a cable is the greater is the facility for leakage, as every additional knot gives additional opportunity for the escape of the current through the insulating cover. Therefore the resistance to this leakage is more and more broken into, so to speak, or opposed as the power of leakage is increased; and as the total resistance decreases the current increases (supposing the same battery power to be employed). The resistance for every knot obviously remains constant if every added length is precisely similar to the previous lengths of any one cable; for if one knot of cable gave a total insulation resistance of 500 million ohms—that is, 500 millions per knot—five knots of the same would give a total of 100 millions, still 500 millions per knot, and 10 knots would have a total or *absolute* resistance of 50 millions or 500 millions per knot. This shows that, in comparing one cable with another, similar in all but length, the longer will have the smaller absolute insulation resistance, and must, therefore, cause a larger deflection under the conditions suggested. The one knot just mentioned has the resistance per knot all concentrated as it were in that length; the longer cables having the same resistance per knot must have a proportionally less total resistance, this total being divided by so many additional knots, each of which reduces it. Any difficulty about this matter arises from confusing the conductive and the insulation resistance. A beginner seems naturally to conclude that the reason why a longer cable gives a larger deflection than a short one is because its resistance is greater, whereas it is just the reverse. He would see this at once if, instead of passing a current through a million ohms as he did when finding the constant, he used a smaller resistance, as eight or nine hundred thousand. His deflection would be larger—instead of 300 divisions, as suggested, he would get, probably, 400 or more. We have discussed this point somewhat at length to prevent any confusion of ideas which we know is felt by many who can take an insulation test but are uncertain about its meaning.

It has been stated that a megohm is generally used for taking the constant in this test. This amount of resistance is not a single coil of wire of a million ohms, but consists of 10 coils each of 100,000 ohms contained in a box and so arranged that one or any number of them can be put in circuit as required. If there should not be a megohm at hand the constant must be found by the next best method. A resistance box with 10,000 ohms is always to be found in the testing room, and with this the operation can be performed. It is necessary to use the same battery power as that employed for testing the cable, but if a current from 200 cells were permitted, the deflection would be far beyond the limits of the scale. The proper course under these circumstances is to find the E.M.F.* of the 200 cells, that is, to find how much stronger the whole number is than one cell; for in any number of cells joined up together we should never find all of equal strength, and 200 would not give a deflection 200 times larger than that given by one of the number. We must postpone explaining how to measure the E.M.F., and assume for the moment that the whole battery is 180 times stronger than one cell. We will now join up one cell, with a resistance of 10,000 ohms and a shunt, not forgetting to put one end of the resistance to earth by a leading wire. On depressing the battery key a deflection will follow, its value being regulated by the resistance of the shunt. We will suppose a shunt of a certain resistance gives a deflection of 300. This amount multiplied by the multiplying power of the shunt will give us the number of divisions which this one cell would give if no shunt had been used. As the E.M.F. of the 200 cells is 180, by multiplying the value just found by 180 we get the number of divisions which the 200 cells would give through 10,000 ohms if no shunt were employed. To find the actual value of the constant we must again multiply this last value by 10,000, and we have the amount in millions. At first sight, this may not appear to result as a matter of course when comparing the explanation in No. IX., where the constant was obtained by operating with a million ohms directly. In that example we found the value at one operation, and the learner may not at once see clearly that we should get the same value whether we used 10,000 or a million ohms through which to test. Turning back to that example, we found that, with the 200 cells, we had 300 divisions, with a shunt of 150 multiplying power through one million ohms, getting thus 45,000 as the number of divisions which would have resulted if no shunt had been used. We therefore multiplied this by one million to get the value in millions. Let us now see what number of divisions we should have as the deflection with the same battery through 10,000 ohms only, if no shunt were used. Remembering that the strength of the current, and, consequently, the deflections caused by it, increases in the same proportion as the resistance of the circuit decreases, it is plain that we should have a deflection 100 times larger than that obtained when the million was employed—instead of 45,000 it would be 4,500,000—multiplying this by 10,000, we have 45,000 millions, as before; or 4,500,000 in tens of thousands is the same as 45,000 in millions. In this comparison we have merely worked with the calculated values, which in practice we could only obtain

* The expression for electromotive force.

Digitized by Google

by the devices previously explained, such as the shunts and the necessity for using one cell with the 10,000 ohms resistance. It would be difficult to get precisely the same amount for constant if both processes were tried, though we have assumed the fact. If with the megohm and 150 multiplying power we have 300 divisions, we ought with the ten thousand to use a shunt of 15,000 multiplying power to give us the same number of divisions, and we could only do this by using one cell first and calculating the value for the whole battery. To carry out a comparison of the two operations fairly the value for the battery should be considered for both.

We may finally look at them in another way, which will also give additional light if any uncertainty yet lingers in the learner's mind. The strength of the current C is represented by the deflection, and it is or varies inversely as the resistance R and directly as E the E.M.F. In reducing this statement to the form of an equation we may regard E as representing or standing in the place of the constant, for it is equal in both cases. We suppose the same battery power to be used, first with the megohm and then with the 10,000 ohms, and the constant is that which results from the employment of this particular E.M.F. Instead, therefore, of writing $C = \frac{E}{R}$, we may put it in the first case $300 \times 150 = \frac{E}{1 \text{ million}}$, or $45{,}000 \times 1$ million $= E$, which stands for "the deflection we should get without shunt is directly as the power determining the constant and inversely as the resistance in circuit," or reducing, "45,000 millions is proportional to or measures the constant required."

In the second case, $300 \times 15{,}000 = \frac{E}{10{,}000}$, or 45,000 millions is the constant. The resistance of both battery and galvanometer is omitted, as is often the case in practice.

In order to show that he thoroughly understands the meaning and course of action of this test, more especially when applied to a cable, the student should be able to answer the question, "Why does the spot move first in one direction over the scale and then immediately commence returning and constantly move back again towards its starting point?"

The action is as follows:—When the cable is charged by depressing the battery key, and the current is also allowed to pass through the galvanometer coils by removing the short circuit plug (or putting down the short circuit key, as the case may be), a deflection, say towards the right hand, immediately follows. The battery key being kept down, the current constantly passes, always in the same direction, through the galvanometer; but the deflection has changed and is towards the left hand. Knowing that this will last while the current is kept on, the learner's first idea would probably be that the spot is, as it were, being constantly driven back by it, as if its passage through the galvanometer were reversed. If the short circuit plug be returned to its place, and the current thus be cut off, the spot returns to zero at once, and it would be just the same if the direction of the current had been originally on the other side. The return to zero is in the same direction as that in which it had been previously moving. Again, if when the cable was charged and the path through the galvanometer was open, any conducting matter in connection with earth touched the end of the copper conductor, the charge would be put to earth, and the spot would rush away in the direction originally followed when the battery key was first put down. Taking these facts into consideration the answer to the question is presented, if, at the same time, the conditions of a cable in view of its identity with a condenser are remembered. We remarked in a former number that an insulation test was in one sense similar to a copper resistance test, inasmuch as in both cases a complete conductive circuit was formed (see Fig. 19). But though sufficient for a fairly good understanding of the former test by a beginner, it is a fact that other conditions are involved, the consideration of which would carry us too far at present. We must be content with saying that the first deflection seen after charging the cable is due to the rush of the current to effect this charge, and the apparent backward movement of the spot is caused, according to one view, by the increasing resistance presented by the insulating cover, thus tending to lessen the deflection, and as others think by a compound influence depending on various conditions. Anyhow, the deflection is really always in one direction from the first, and it is not forced back by the current, but its position on the scale is the result of a balance of forces mutually contending.

In the next number of the series we shall consider the operation of joint testing.

CROMPTON'S COMPOUND MACHINE.

BY GISBERT KAPP.

(CONTINUED FROM PAGE 115.)

The electromotive force in the armature is directly proportional to the variation per unit of time in the number of lines of force passing through the coils. If the armature contain no iron core, we have only to consider the lines of force bridging the pole pieces of field magnets; but if it contain a core we must also consider the lines of force created in it by the armature current itself. We may call the former primary, and the latter secondary lines of force. The part they play in the action of the compound machine is so important that a slight digression into the theory of the Gramme ring will here be necessary.

It is well known that, whilst the ring rotates and sends a current out, the primary lines of force are pulled forward in

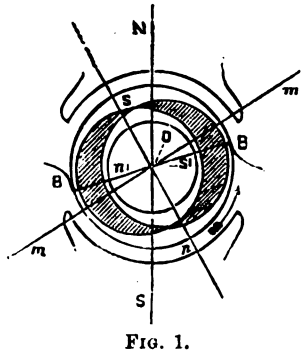

FIG. 1.

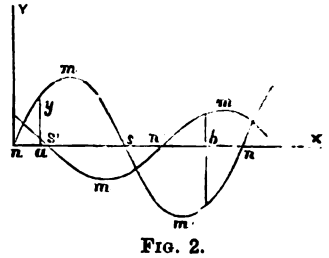

FIG. 2.

the direction of rotation by the curl of the current in the armature wires. Let N O s be the angle by which the field is thus shifted (Fig. 1), then we can consider $s\,n$ a line of symmetry, and imagine that the N pole of field magnet has shifted until it came opposite s, and the S pole until it came opposite n; s and n being the points of greatest polarisation in the Gramme ring. The lines of force divide symmetrically to right and left of $s\,n$. If we were to draw them into the figure we would find that no lines pass the primary poles s and n, but that going to the right or left, line after line, would have to be added until on the diameter $m\,m$ their number becomes a maximum. Graphically, this can be represented by the shaded space, the tangent of inclination between the two curves enclosing that space on any diameter being proportional to the electromotive force which would be created in a coil the moment it passes that diameter. It will be seen that on the diameter $m\,m$ the angle of inclination is *nil*, and, therefore, the brushes ought to be placed in this neighbourhood. Say we place them on the diameter B B. Now, the current traversing the Gramme ring will itself tend to polarise it in the points s' and n'. In many ordinary machines these secondary poles are very much weaker than the primary poles $n\,s$, and their influence can almost be neglected; but in compound machines they become sometimes a source of trouble, and must, therefore, be taken into consideration.

Imagine the Gramme ring cut at n, and spread out into a straight line, then we shall have a diagram for the lines of force something like Fig. 2. This diagram must not be considered drawn to scale; it is not intended to give exact numerical values, but merely to illustrate the idea of primary

Digitized by Google

and secondary lines of force. The ordinates of the curve n, m, s, m, n, represent number and sign of primary lines of force along the circumference of the ring n, s, n. As the electromotive force is proportional to the change in that number, it can be geometrically represented by the numerical value of the tangents to the curve, and analytically by the first derived of the ordinates y in regard to the circumference $\left(\frac{dy}{dx}\right)$, supposing the function of the curve itself to be known.

Similarly, we find $s' m' n' m'$ to represent the secondary lines of force, and the E.M.F. actually created in a coil, passing a given point a, can be represented by the combined effect of the two curves. It will be seen that the tangent to the primary curve at that point is positive, whilst that to the secondary curve is negative. In this point the secondary lines oppose, therefore, the action of the primary lines, and the E.M.F. resulting is due to the difference of the two. In point b, however, both tangents are positive, and the resulting E.M.F. is due to the united effect from the two sets of lines of force. A very simple, although, perhaps, not strictly accurate illustration of this can be obtained by applying the parallelogram of forces to represent the intensity of magnetic poles.

Let O s (Fig. 3) represent strength and position of primary pole, O s_1 the same for secondary pole, then O s o will represent strength and position of an imaginary pole, the influence of which is approximately equal to that combined from the two component poles. The brushes B B are necessarily in line with the secondary pole s', and in order to utilise all the E.M.F. available in the ring, the resultant O s o should

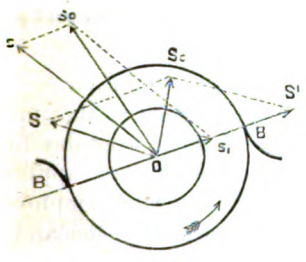

Fig. 3.

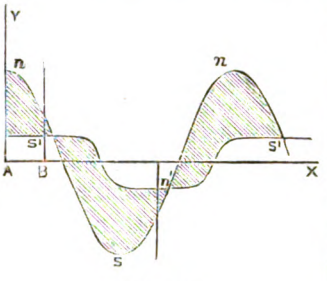

Fig. 4.

be at right angle to O s, that is to say, at right angle to the diameter through the brushes.

Now, suppose in the case of an ordinary shunt machine the external resistance suddenly and considerably decreased. The natural consequence will be an increase of armature current and a decrease of E.M.F at the brushes, which, in its turn, lowers the exciting current and intensity of the field. Unless the field magnets were greatly over-saturated, this reduction in the strength (or, we should say, number) of the primary lines of force will be sensible; and, occurring at the same time as the distorting influence of the armature current is increased, will result in the shifting forward of the primary pole and a reduction in its intensity. Let S be its new position and S_1 that of the new secondary pole. If we now determine the resultant O S o by the diagram of forces, we find that the angle B O S o differs considerably from a right angle, and thus, through the decrease in the external resistance, the brushes have come to be in a wrong position, and, unless adjusted again, will be found to spark heavily.

But, even where no very great variation in resistance takes place, the brushes of ordinary shunt machines are sometimes liable to sparking. The reason seems to be that, owing to there being a finite number of sections in the commutator, the E.M.F. at the brushes is slightly undulating. This gives rise to current-waves in the shunt coils which, under certain conditions (a great number of shunt coils and a weak field), get intensified by a sort of self-induction and cause considerable and quickly recurring variations in the intensity of the field. In consequence of this the brushes are always in the wrong position either one way or the other, and sparking is the result. This difficulty can be overcome by using shunt wire of sufficiently low resistance to get an over-saturated field, or by winding a limited number of main coils over the shunt and thus compounding the machine. The main current seems to exert a steadying influence upon the shunt current, although there are not sufficient main coils to keep the E.M.F. up were the machine accidentally short circuited.

The diagram given in Fig. 2 can be brought into a more convenient form by plotting the numerical values of the tangents to the two curves. We thus obtain Fig. 4.

The distance of any coil from the primary north pole is measured on the horizontal A X, and the corresponding ordinate contained within the shaded space between the two curves gives the E.M.F. of that coil. From this it follows that the area contained between any two ordinates and the two curves gives the aggregate E.M.F. of a group of coils filling the space between these ordinates. The total E.M.F. of the armature will, therefore, be represented by the shaded area contained between the two verticals B B, which represent the brushes.

In computing this area the shaded part between s', B, s, and n' is to be counted positive, that between n and s', and n', n and s', negative. The maximum E.M.F. will be obtained if the position of the brushes corresponds to the points of intersection between the two curves. These points can be found while the machine is at work by the following simple experiment:—Take a fine insulated wire, doubled up so that its two bared ends come to be side by side and about one-eighth of an inch apart. By touching the surface of the commutator with both ends sparks will be observed, the brilliancy of which give some idea of the electromotive force in those coils which correspond to the points touched. Where the brushes touch hardly any sparks at all should be obtained, and if this is found to be otherwise the brushes must be readjusted.

By inserting a voltameter into the circuit of the testing wire sufficiently accurate readings could probably be obtained, by which the curve of E.M.F. could be plotted from actual experiment.

As long as speed and external resistance remain unchanged there can always be found one best position for the brushes. This is the case with ordinary dynamos working always under the same conditions. The secondary lines of force, although present, can always be compensated for by a proper adjustment of brushes.

Not so with compound machines. They have to work under great variations of external resistance and current, necessitating, as was shown in the beginning of this paper, also a certain variation in the electromotive force of armature. If the brushes happen to stand in the best position for one certain current, they will not stand so for a different current, and thus, where the conditions of working are being continually varied, the brushes are, so to speak, continually in the wrong place. It remains to be seen how far this is injurious to the working of the machine and its regulating power. For this purpose we will, by the aid of the diagram (Fig. 4), analyse the action of the machine, assuming, at first, that no current is taken off, and then that a gradually-increasing current is allowed to flow through the external circuit, the resistance of which we assume to be gradually lowered until the maximum current which can be safely permitted has been obtained.

(TO BE CONTINUED.)

Dewsbury Theatre.—The Yorkshire Brush Electric Light and Power Company, of Leeds, are lighting the above theatre by their system of arc lamps. One lamp is erected at the front of the building, one in the auditorium, and one focussing light on the front of the stage. At present the effect is very good for scenic purposes, and the managers are quite satisfied with the result. The company are now fixing two more lamps at the wings on either side of the stage, in order to counteract the shadows cast by the ballet girls from the intense light of the focussing lamp. The dynamo is driven by a small cylinder engine in a turning shop adjoining. The installation is under the supervision of Mr. A. Gay, one of the company's electricians.

THE ELECTRICIAN.

TO CORRESPONDENTS.

All letters intended for insertion in THE ELECTRICIAN, *or containing questions, must be accompanied by the name and address of the writer, not necessarily for publication, but as a proof of good faith. No notice whatever will be taken of anonymous communications.*

All communications to be addressed to 396, *Strand, London, W.C.*

We cannot undertake to return drawings or manuscripts, and must, therefore, request Correspondents to keep copies.

SUBSCRIPTIONS.

THE ELECTRICIAN *can be had, by order, from any newsagent in town or country, at the various railway stations; or it can, if preferred, be supplied direct from the office, on the following terms (paid in advance):—*

Quarterly	4s. 10d.
Half-yearly	9s. 9d.
Yearly	19s. 6d.

P.O. Orders to be made payable to James Gray, at West Strand Post Office.

NOTICE.

VOL. IX. of THE ELECTRICIAN,

STRONGLY BOUND, WITH COPIOUS INDEX,

NOW READY.

Price 10s. 6d.

CASES FOR BINDING ALSO READY. Price 2s.

Order of any Bookseller or Stationer.

SINCE 1878.

At this season of the year, when the wings of time flap so loudly that we are compelled to hearken; when, much against our inclination, we stand idly watching the flight of a departing year, thoughts arise which, be we never so matter-of-fact, or never so self-complacent, make us serious if not sorrowful, sober if not penitential. We cannot call it back even if we would live the old year over again, and perhaps few of us would like to do that. The pleasures and the triumphs which are fast fading out of sight carry with them also the pains and the disappointments, and these latter we willingly bid good bye to for ever. At any rate, whatever may come of the successes, the failures are all our own, and from the reader's point of view, if not from the writer's, this is much to be thankful for.

In this frame of mind it is natural, perhaps, that we should look back upon the years that have passed since we first made the acquaintance of our ever indulgent readers. That the acquaintance is not of long standing is one ground for satisfaction. So friendly have grown our relations, so helpful and cordial have become our intercourse, that we can hardly believe we first began to know each other less than five years ago. Those years, few as they have been, have served to establish us well in the friendship of our clients; but they have also marked an epoch in the science with which we are all alike deeply interested, and this has made the period seem long, for it has been a most eventful one. Hopeful as we were at starting, we had but a dim perception of what would really come of our venture. We could not foresee that what has happened in the interval would come to pass, nor can we pretend that we hoped it would. But fortune has favoured us all in this matter. Not that we presume to think we have forced fortune's hand; by no means. What we think and say is that fortune's hand was ready, and that we helped her to open it wide.

And, on the whole, we think we are warranted in saying this much of ourselves—that we did assist fortune a little in conferring her bounty on mortals here below; for, if it is true that fortune favours the brave, it follows that fortune has favourites—in other words, that she does not despise instruments, that perhaps without instruments she does not condescend to favour anybody. And in that case we have a claim to be considered an instrument of a very useful sort put into her hand just at the right nick of time.

In the address we put forward at the outset of our career we remarked that the progress of electrical science, the application of scientific discoveries to the wants of everyday life, the extended commercial interests involved in these applications, the importance of the subject to thousands employed in producing or in promoting them, seemed to demand a public journal specially devoted to those interests. Events have proved that our estimate was not mistaken, but the most sanguine of prophets would hardly have predicted how great was the coming need for, and how useful such an organ would be. We were sufficiently modest in our expectations, and they have been more, far more, than realised. At that time, that is to say in the summer of 1878, we were on the eve of great discoveries and the formation of new industries. We saw this, and desired to promote them in every way that a journal could; but, to be modest still, we confess to not seeing how vast would be those industries, how important would be their results.

Just then we were recovering from the astounding discoveries of Professor Graham Bell; the wonderment created by the invention of the telephone was beginning to give place to speculation as to what would be its practical usefulness. A fresh impulse was given to this aspect of the matter by the hardly less curious, if less obviously useful, discovery of the microphone. These discoveries, and many others of a like kind in the electrical world, were, we argued in the address to which we are referring, useless if they remained hidden in the note books of the laboratory, or stowed away in the annals of scientific societies' journals. They must be made public, intelligible, popular, if they were to become useful and were to be applied to the practical purposes of civilisation. There were also the existing industries to be considered—rapidly-growing industries—with enormous capital invested in them already, and absorbing more and more capital every succeeding year. Their successful working, both as regards efficiency and remuneration, was largely dependent on the perfecting of electrical

Digitized by Google

appliances—chiefly, of course, of telegraphic instruments. Without these the working of lines at a profit would be impossible, and increased facilities out of the question. Add to this the encouragement needed for original research to further these aims, first by giving widest publicity to its results, secondly by finding a market for its utilisation. Lastly, with a view to the future, we promised ourselves to lend a helping hand to the electrical student, seeing that upon him would depend the final development of applied electrical science. The student, in our view, not only includes the man who makes the study of pure science the aim and object of his life, but also the man who takes the principles to hand and applies them in new combinations to the construction of apparatus designed to ameliorate the conditions of life.

Such, roughly indicated, were some of the objects we had in view. How far we have consistently or successfully followed them must remain with our readers to judge. But about one thing we shall all be agreed—namely, that the four-and-a-half years during which we have been at work have been most encouraging as well as most eventful. The telephone has become a utility as widespread as it is novel; and the microphone, which at first looked like a useless marvel, quickly found its place as a helpmate to its immediate predecessor. Both combined are now playing their part as the indispensable handmaids of commerce and social life. As to the telegraph, it has extended overland as rapidly as we could desire, and under sea perhaps rather faster than we need. But the appliances are keeping well in the wake of the requirements; and, if past experience may guide us in this matter, the increasing means now at our command to dispose of telegraphic traffic will largely help to swell it, and give to enterprise its reward. Duplex and quadruplex telegraphy applied to submarine cables have more than paid their discoverers, and in due time will amply repay their patrons.

There was one other subject we had in our minds, though we did not make much of it at the time. The electric light was just then beginning to make itself known for ordinary public purposes, but only beginning. How few and insignificant were the improvements then accomplished is evident from our pages at that date. For a long time the patents relating to electric lighting did not constitute more than five per cent. of our weekly summaries of recent inventions. Now they are, probably, nearer fifty per cent. Nevertheless sufficient progress had been made to show that in a comparatively short time a formidable rival would make its way in public favour to the old-established gas lighting agency. How short that time would be we certainly did not anticipate, but in this we were not singular. If anybody else was wise enough to foretell its extraordinary and unprecedented development in the course of three or four years, all we can say is that we have ungrudgingly helped to make his prophesy come true. The practicability of the electric light is now fully established; its popularity is well assured; all that remains is for scientists and experimentalists to render it tolerably cheap. From week to week our pages testify to the efforts being made in this direction, and when another new year comes round we doubt not that the record of substantial progress will be as gratifying as it has been in the last. Those birds of time who are flying away with all that we have done, scattering our departed selves on the revolving age below, are followed by others not slower on the wing, but also not less indulgent. They will have the happiest new year who, seizing the fleeting opportunities, are fortunate in doing something worth leaving behind them on the ages yet to come. May fortune so favour all our kind friends.

DANGERS TO ELECTRIC LIGHTING.

(FROM A CORRESPONDENT.)

One frequently meets with paragraphs in the non-technical press concerning the—for the most part visionary—dangers *from* electric lighting, but our theme is the converse of this—the dangers *to* electric lighting. These come about in various ways, one of which is this same ignorant writing we have just referred to, which tends to scare would-be users, the class especially, and it must, after all, be the class composing the majority of those who will ultimately adopt the light, which only cares for the resultant light and its cost, not heeding the way or means of its production. How many out of the millions using gas know the details of gas making? But neither is our theme with this danger. The danger we would draw our readers' attention to is a danger from within, and we have reason to know it is a very real one. It arises from the desire of certain companies and individuals to do immediate business at any cost, with the result, as the head of a large firm said to us the other day, "I'm sick of the whole thing, and have given orders to have the whole plant cleared out at the end of the week." What has brought this undesirable state of things about it may be instructive to examine into a little more fully. The case we refer to is in every respect a typical one, and had success attended the installation a large business was assured to the company. As it is, gas is again in the ascendant, and, as far as the company referred to is concerned, a whole district had better have been omitted from the map of Britain. Without indicating the locality suffice it to say that we, a few weeks since, chronicled the fact of the starting of electric lights in an extensive weaving mill. For a few days all seemed promising—a few lamps were broken certainly, but this was thought little of for a start, and a single dynamo was used, driven by a countershaft from the large mill engines. On our next visit we were not surprised to find that this dynamo had altogether vanished, it was never cool enough to touch, and two of quite a different type had been substituted, with but small improvement. The company's electrician declared the speeding was at fault, but as he had had absolutely every thing under his own control from the beginning the fault lay with him. The speed was altered, still lamps broke. This breakage might have even been tolerated, for the light, when good as it was occasionally, was a great advance on gas. But now arose the difficulty of keeping the dynamos running long enough continuously, for nightwork is the rule and not the exception in this mill at certain seasons. We were told that a set of brushes hardly lasted for an ordinary run, that the armature where it is in contact with the brushes is hopelessly cut and scored, so that sparking is continuous. On our several visits to the mill we have generally been lost in wonder at the way things were managed by the Electric Light Company in marked distinction to every other department. It will hardly be believed that in what was avowedly a test installation—an installation at the company's own request—there was not a single instrument for measuring current or illuminating power of lamps, even in the roughest way; the leads simply went direct from the dynamo to the departments where the light was used. We have no idea why the lamps broke, for we know nothing of the strength of current, E.M.F., or anything else. We had our suspicions all along, and we greatly regret that they have now been fully confirmed. That the lamps were faultless is not to be supposed, for it was manifest that their resistances, as they broke in all parts of the circuit, were far from uniform. This could be seen without the breakage test, which was too frequently involuntarily made. We have gone thus fully into one particular case rather than give instances from various districts, but we are sure they could easily be supplied, and would form instructive reading.

SOUTH AFRICAN TELEGRAPHS.—The revenue derived by Cape Colony during last October from telegraphs was £4,427 14s. 9d., against £5,603 6s. 1d. in the same month of 1881, or a decrease of £1,175 11s. 4d.

MR. STAITE'S IMPROVED APPARATUS FOR LIGHTING BY ELECTRICITY—1847.

It is well known that Mr. Staite was one of the first inventors in the field of electric lighting, and it is interesting to know how his ideas compare with those of to-day. His form of lamp is very little known, hence we do not hesitate to reprint the following description from an old volume of the *Mechanic's Magazine*:—

Fig. 1, is an external elevation of the apparatus; fig. 2, a sectional elevation of it on the line, W *x* (fig. 3); and fig. 3, a horizontal plan on the line, *y z* (fig. 1). Mr. Staite's description is as follows:

M, and N, are two cylinders of carbon prepared as is afterwards described, which are used as the electrodes, that is to say the current of electricity is passed from one to the other as they stand end to end, their ends being separated by an interval of from less than one-twentieth to about half an inch, according to the power of the electric current used. The upper electrode, N, is passed vertically through a hole in the summit of the metallic support, or tripod, K, and fixed by binding screws. The lower ends of the legs of the tripod are passed through holes in the circular main-plate, A, of the apparatus, and secured in their positions by collars and nuts, but are carefully prevented from coming into metallic contact with the plate, A, by means of washers of some dry, hard non-conducting wood. The legs terminate at bottom in set screws, L L, which connect them with a conducting wire, which passes round through the extremities of all the legs, and is connected with one end of the coil of the regulator, *r*. The other end of this coil is led to a clamp, R^2, with a set screw fixed at one side of the square wooden basement, B, on which the whole of the apparatus is built, and which is mounted on four short supports, *b*, *b*, *b*, *b*, at its corners, to allow room for some parts of the apparatus which project below the basement. The main plate, A, is firmly attached to the basement, B, by four pillars, *c*, *c*, *c*, *c*; C, and D, are cones which spring from opposite sides of the apparatus, their common axis passing at right angles through the centre of the main-plate, A, which is bored out for the purpose. The apices of these cones are perforated, to admit the perpendicular central shaft, O, which has a socket for receiving and holding the lower electrode, M, at its upper end; and this socket is furnished with set screws for securing the electrode in an upright position in its centre, even though that electrode should happen

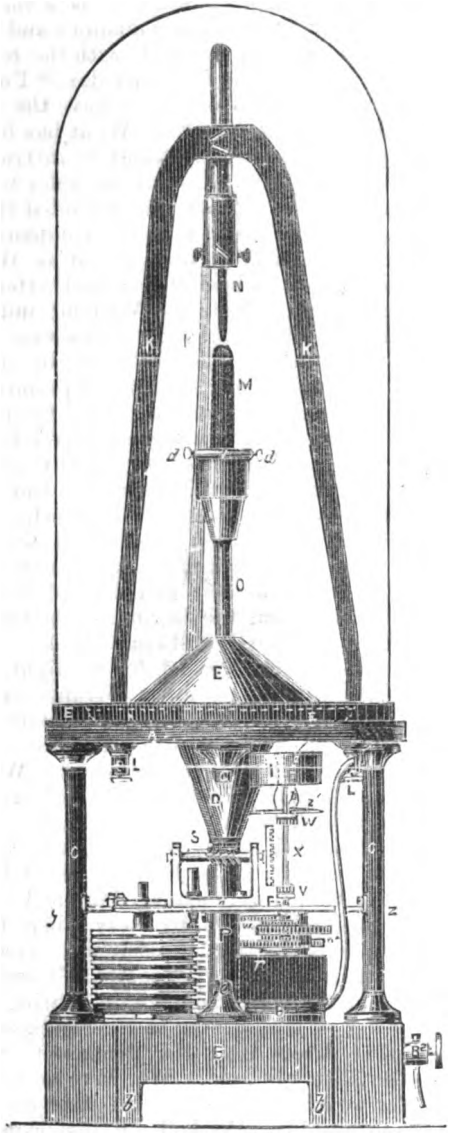

Fig. 1.

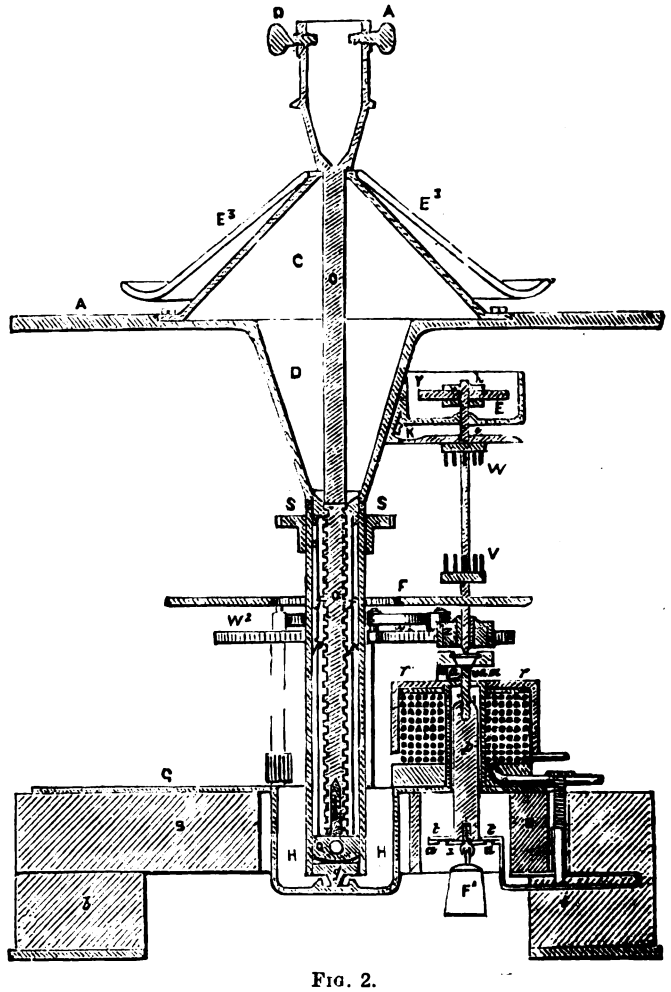

Fig. 2.

to be of smaller size than the socket. At the bottom the socket is made of a conical form, in order to keep the lower end of the electrode steady and concentric, so that it may be properly adjusted by set screws, *d*, *d*. This shaft, O, has a smooth straight part, below its socket, for a length equal to the distance between the apices of the fixed cones, C, and D, which is equal to the amount of rise which the shaft admits of, to compensate for the wear or shortening of one of the electrodes, while the light is in action; this smooth part of the shaft moving freely through the hole in the apex of the upper cone. Below this smooth part the shaft is continued for an equal length, screwed; the threads of the screw giving about one-twelfth of an inch of rise for every turn. This screwed part works through a nut, *e*, which is set tight in the apex of the under cone, D, and passes down the centre of a hollow cylinder or tube, P, which is slotted internally (as shown at *f*, *f*, in figs 2 and 3). A little cross piece of metal, Q, is set tight on the bottom of the shaft, O, by being screwed

Digitized by Google

fast into its end, and this cross-piece, Q, (which is more particularly described in Fig. 4) fits across the tube, P, taking into the slots or grooves on each side, so that it can slide up or down in them. When, therefore, the tube, P, is made to revolve, it carries the shaft, O, round with it, by means of the sliding cross-piece, Q, and makes it to rise or sink by its screw working in the fixed nut, *e*, so that the shaft, O, carrying the electrode, M, in its socket, has a rotary motion combined with its vertical motion for the purpose of equalising the wear of the electrodes on all sides. The tube, P, turns on a pivot, *g*, which works in the bottom of a circular box of metal, H, which is screwed into a hole of sufficient size in the bottom of the brass-plate, G, which is fixed to the upper surface of the wooden basement, B. The touching surfaces at the pivot, *g*, are coated with silver; as that metal presents a surface peculiarly fitted for receiving the current of electricity. The upper end of the tube, P, receives the outer part of the fixed nut, *e*, on which the outer tube turns, and is steadied as on an axis. On the upper part of the tube, P, a worm-wheel, S, carrying forty teeth, is attached, which is made to revolve by a horizontal double-threaded tangent-screw, T, the pitch radius of which is one-tenth of an inch. To one end of the screw is attached a crown-wheel, U, carrying forty teeth, which is actuated by pinions, V and W, on an upright spindle, X. The pinions are at a somewhat greater distance apart than the diameter of the crown wheel, U, and gear into it from opposite sides, so that when the spindle, X, is raised a little, the lower pinion, V, (having eight teeth,) is geared into the lower side of the crown wheel; but when the spindle is sunk, the lower pinion is thrown out of gear, and the upper pinion, W, gears into the upper side of the crown wheel; and the spindle continuing to revolve in the same direction as before, imparts a reversed rotation to the crown wheel. When the spindle is kept at a medium degree of elevation, neither of the pinions is in gear with the crown wheel, so that it remains quiescent. This spindle, X, is kept in its position by working through a hole in the middle plate, F, of the apparatus, which plate is attached firmly to three of the pillars, *c*. The upper end of the spindle works through a hole in the centre of the bottom of a circular brass box, I, which is fixed to the side of the under cone, D, or to the under side of the main plate, A. The box, I, contains a centrifugal regulator, Y, which consists of a bit of watch-spring bent into the form of the letter S, carrying two little weights, *hh*, at its ends, and fixed horizontally across the top of the spindle by the middle part of the spring, which fits into a cleft in the top of the spindle, and is secured by a small nut. When the spindle is made to revolve too fast, the weights at the end of the spring fly outwards by their centrifugal force, and begin to touch and rub against the sides of the circular box, I, which friction checks the motion. This description of governor preserves the motion more uniformly than the ordinary sort of fly, which acts by the resistance of the air. Just below this centrifugal governor there is a cross-piece, *i*, inserted through a transverse hole in the spindle, X, so that when the spindle is as its medium degree of elevation, that is to say, when its two pinions, V and W, are neither of them in gear with the crown wheel, the ends of the cross-piece, *i*, meet a stop, K, which may project from any fixed part of the apparatus, such as the cone, D, and so stop the revolutions of the spindle; while, as soon as the spindle is raised or lowered, the cross-piece, *i*, no longer meets the stop K, but passes over or under it, and allows the spindle to commence its revolutions just before one of the pinions gears into the crown wheel. The spindle, X, is actuated and kept with a constant tendency to revolve in one direction by a toothed wheel, Z, keyed on to it just below the middle plate, F, and this wheel is driven by a train of wheelwork, W^2, supported between the middle and bottom plates, F and G, similar to ordinary clockwork, and which is driven by a spring in a barrel, *l*, acting on a fusee, *m*, driven by a cord or chain; or the wheelwork may have any other contrivance as its prime mover, as, for instance, a common barrel with a cord and weight. The wheel, Z, is of such thickness that the motion up and down, which the spindle X admits of, will not ungear it from the next wheel in the driving train.

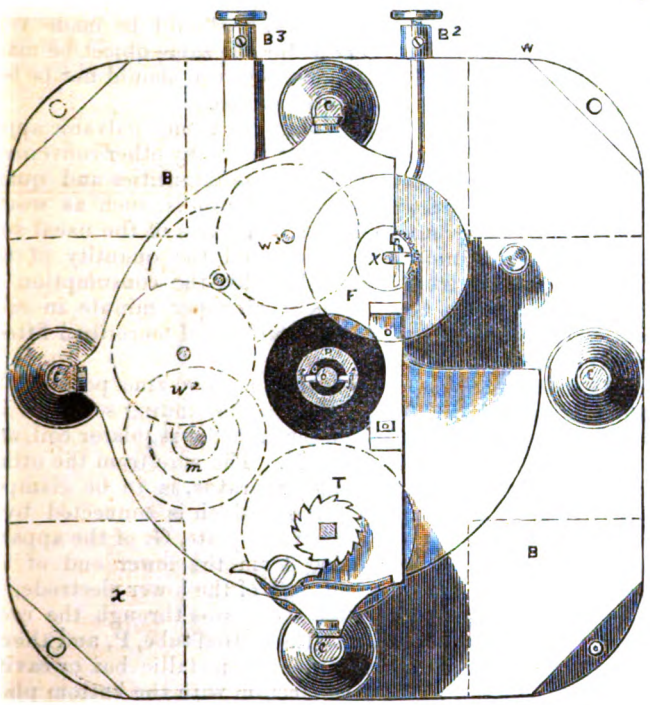

FIG. 3.

The mode in which the spindle, X, and its pinions are raised or lowered, so as to drive, or stop, or reverse, the motion of the crown wheel, U, and thereby of the electrode, M, according to the exigencies of the light (as, for instance, when the electrode becomes worn, or any alteration takes place in the power of the battery,) is exceedingly ingenious, and is as follows:

FIG. 4.

The bottom of the spindle terminates just below the driving wheel, Z, and rests on a plate of ivory, *n*, which is supported on a short upright stem of brass, *o*, which has its lower end screwed into a hole in the top of a solid cylinder of soft iron, *p*. This iron can move freely up and down in the central hole of a reel, *q*, round which a quantity of insulated copper wire is wound: one end of this wire is led to the binding screw, B, as before mentioned, which connects it with the positive wire of the galvanic generators, and the other end to the wire which passes through the binding screws, L. The reel, *q*, of the regulator is fixed firmly to the wooden basement, B, and a cap, *r*, of soft iron, fits over it; but the iron of the cap does not extend quite to the centre of the hole in it (through which the brass stem, *o*, passes), the central part of the top of the cap being of brass soldered to the iron, of one-half of the diameter of the iron cap itself. The action of the electricity in the coil of the regulator, R, causes the iron centre, *p*, to rise or fall, according to the quantity of electricity passing, and in so doing, the spindle, X, which rests on it, to rise or fall with it. There isa little eye attached to the bottom of the iron centre, to which is suspended a counterpoise, F^1 (an assortment of such counterpoises being kept for use), of such weight as to allow the iron centre to be just in equilibrium, or just ready to rise, when the distance between the electrodes is such as to allow the electric current to flow freely enough to produce a steady and certain

Digitized by Google

light. There is also a little ledge, *s*, around the lower end of the iron centre, on which rests a disc, *t*, of brass, of about the size indicated in the drawing, fig. 2; which (when the iron centre falls below the neutral point) becomes supported around its outer edge by a circle of brass, *u*, and is left behind on it, when the iron centre continues to descend, thus relieving it of its weight; while on the other hand, if the iron centre is disposed to rise above the neutral point, it has to lift the whole weight of the brass disc, *t*. This arrangement gives the iron centre a tendency to remain stationary at the neutral point, which is that point at which the elevation of the spindle, X, enables the cross arm, *i*, to come into contact with the stop, *k*, and arrest the rotation, and so prevent unnecessary working of the machinery, until the electric current has varied so much as to render desirable an adjustment of the distance between the electrodes; which the iron centre effects, as before described, by rising or falling.

The neutral position at which the iron centre, *p*, should rest, is when the top of the iron centre is as far below the top of the regulator reel as is represented in figure 2.

The brass ring, *u*, which supports the equilibrium weight, that is the brass disc, *t*, is secured at the proper height by being attached to a sufficiently stiff strip of brass, *w*, of a certain length, and which is fixed by its other end to the other side of the wooden basement, B. The brass ring, *u*, can be adjusted to the requisite height exactly, after the apparatus is made, by a milled-headed screw passing through the wooden basement, and screwing down on the supporting brass strip (not far from *u*), so as to depress it to the right position.

The sliding cross-piece, Q, before adverted to, is constructed in the manner separately represented in fig. 4. A spring, Q, (of thin hard brass, for instance,) is attached to one side of the cross part by a small screw, so that when the cross-piece is placed in the slots of the tube, P, the spring always remains in close though not forcible contact, against the sides of the slots, so as to ensure a good conduction to the electric current which has to traverse the shaft, and enter from the cross piece into the slotted tube.

The tangent-screw, T, is made not quite horizontal, but inclined at an angle of one in twenty, because the lower pinion, V, is smaller than the upper one; and therefore it is necessary that the lower edge of the crown-wheel, U, should be tilted nearer to the axis of the spindle, X. The lower pinion is made smaller, in order that it may the better wind down the main shaft, O, after it has screwed itself up, until the ends of the electrodes come into firm contact, lest it should stick in that position.

The screw, No. 1, which fastens the stand, 3, of the tangent-screw to the middle plate, F, passes through a hole, 4, enlarged sideways in the stand; so that by only loosening the screw, 1, the stand may turn on the other screw, 2, as a centre, so as to allow of the tangent-screw, T, being adjusted to the right distance from the centre of the wheel, S, in order that it may work properly into its teeth, or, when required, to throw the tangent-screw out of gear with it altogether.

The thread of the screw of the main shaft, O, should be of a square form, so that it shall work with as little friction as may be, when supporting the weight of the shaft and electrode.

A cone of white glass or porcelain, E^3, is made to slip over the upper cone, C, of the main plate, and is turned up at the edges (as shown in figs. 1 and 2), to reflect the light better, and to catch any dust and ash which may be thrown off from the electrodes.

A glass shade, which may be ground partially or not, as desired, fits over the electrodes, M and N, and the stand, K, and is screwed down to the main-plate, A, by the brass circle, E, into which its lower edge is cemented, whereby the electrodes are enclosed entirely from the outer air. As soon as they have exhausted the oxygen which is within the glass shade, they are no longer so rapidly consumed. When the electrodes, however, are composed of some inferior sorts of carbonaceous preparations they give light more steadily if a very small quantity of atmospheric air is continually allowed to enter; that is to say, just sufficient to burn away the button of carbon which sometimes forms on the end of that electrode which is not undergoing decomposition by the electric current. When there are no holes in the glass shade to admit of a small quantity of atmospheric air, two light valves may be inserted in the main plate, A, one opening inwards and the other outwards, which would provide for the varying pressure of the air when the temperature is altered by the presence or absence of the light within.

The coil of insulated wire of the regulator, R, should be composed of wire of such thickness as to conduct the electric current quite freely. For an apparatus of the size represented in the engravings it may be about three-sixteenths of an inch in diameter; but if electrodes of a larger size are employed, the wire should be proportionally increased in thickness, and the regulator, R, made as large as the dimensions of the apparatus will admit of, in order that the reel should take a sufficient number of turns of the thick wire; for with wires too thin, considerable heat is evolved from them when transmitting the current. Two circular brass weights, *a a*, fit one over the other around the ivory top, *n n*, which carries the pivot of the spindle, X; their use is to enable an easier and more precise adjustment of the weight on the iron centre than can be effected by altering the large weight, F^1, which is hung at the bottom of the iron centre.

When it is intended to use small currents of electicity, the spindle, X, and all its appurtenances, should be made very light, and the iron centre may for the same object be made hollow with advantage; its sides, however, should not be less than one-twelfth of an inch in thickness.

The electric current may be obtained from a galvanic apparatus of any of the known sorts, or from any other convenient source; and it may be used of various intensities and quantities. A good degree of intensity to use, is such as would be afforded by one hundred cells in a series of the usual sort employed in galvanic apparatuses; and the quantity of the current may vary from that evolved by the consumption of less than one and a half grains of zinc per minute in each cell, to that evolved by the consumption of more than fifteen grains of zinc per minute.

The wire from the positive, that is, the zinc pole of the galvanic apparatus, is clamped with the binding screw at B^2, which serves as the conductor through the regulator coil, and then up to the upper electrode, N. The wire from the other, or negative pole of the galvanic apparatus, is to be clamped with the other binding screw at B^3, which is connected by a slip of metal (copper) to the bottom plate, G, of the apparatus, so that the current passing from the lower end of the upper electrode, N, to the top end of the lower electrode, M, then traverses the central shaft, O, passes through the cross piece, Q, at its lower end, into the slotted tube, P, and thence through its pivot at bottom into the metallic box or cavity, H, which being in metallic connection with the bottom plate, G, leads the current to that plate and thence by the slip of copper to the other clamp, from which it passes in return circuit through the negative wire of the galvanic apparatus. The current, when first applied with the electrodes in contact, flows freely, and that causes the regulator (being properly weighted) to raise the spindle, X, and thus put the apparatus into gear for screwing the centre shaft, O, downwards, and gradually separating the electrodes, whereupon the light begins to appear between them.

Mr. Staite specifies, also, as included under his present patent, the following method of preparing the carbon for his electrodes:

About equal quantities are taken of coal of a medium quality, and of the prepared coke, known as "Church's Patent Coke," and both reduced to a state of fine powder and intimately mixed together. The mixture is then placed in close wrought iron moulds, which may be made either to give the mixture the form of a block, to be afterwards cut into pieces of the required shape, or to give at once to the mixture the form of the intended electrode. In all cases I prefer making the moulded mass of not more than 3 or 4 inches in its least diameter, for when much larger it is liable to have fissures, and not to be of such uniform density. The mixture being placed in these moulds, is subjected to heat and heavy pressure until it becomes consolidated into a very dense and firm mass. And when the mass is in a heated state it is

Digitized by Google

plunged into sugar, melted by heat (without the aid of any liquid,) and kept therein for a short period. It is then taken out and allowed to become cold, when it is placed amongst pieces of charcoal in a close vessel, which is gradually heated until it attains a full red heat, after which the temperature is increased to an intense white heat; at which it should be kept for many hours, or even two or three days, according to the hardness and compactness desired. Or the mass may be a second time immersed in the melted sugar while hot, and the remainder of the process be again repeated as before.

By coating the mass in this way with melted sugar, any pores that may be in it (on its external surface at least), are filled up with carbonaceous matter, and any subsequent drying rendered unnecessary.

However, Mr. Staite limits his claim as to this method to the application of *melted sugar*. A solution of sugar *and water* has, we believe, been before used for the same purpose.

The following are stated to be the best dimensions for the electrodes:

The lower electrode should be as long as can be conveniently manufactured (8 inches, for instance,) when used for ordinary purposes, and it should be of a cylindrical form. The smaller the diameter is the better the light; but the larger the electrode is (in cross section) the longer it will last with a given current of electricity. The upper electrode need not be of any great length; it is well, however, to have it about one-third as long as the lower one, and of half the diameter.

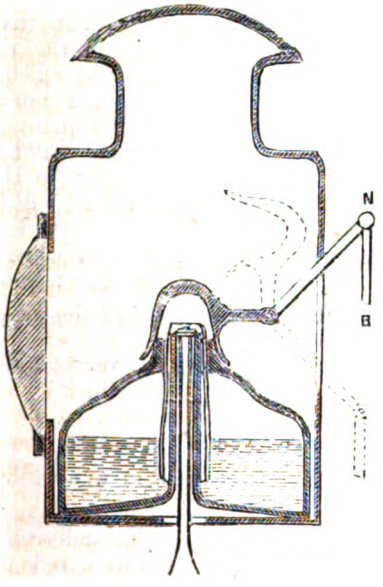

FIG. 5.

Mr. Staite concludes his specification with the following account of a method of employing currents of electricity "to actuate apparatus for effecting the speedy lighting up and extinction or obscuration of signal lamps in which oil, camphine, or other like inflammable fluid is the illuminating substance employed."

Suppose, for example, there are three such lamps with different coloured glasses, say white, green, and red, which are required to be sometimes lighted, and at other times extinguished or obscured, as is usual on railways, and not all at once, but in a particular order of sequence, or each under particular circumstances only, I effect this in the following manner:—The three coloured signal lamps are placed side by side, or they may be placed one above the other. A sectional elevation of one of these lamps is given in fig. 5. N is a bar of metal, having a drop bar, B, attached to it. These bars are for the purpose of working three extinguishers, one to each lamp. The figure shows one of these extinguishers as applied to a lamp; the dotted lines in the figure indicate the position which it assumes when raised up. The drop bar, B, is attached to a clockwork escapement, the detent of which is alternately retained and liberated by the passage of an electric current, and by its mechanical force raises up the bar, B, and causes the light, in whichever lamp it may be, to be put out. The three extinguishers are made to move together, to save the necessity of each being provided with a separate extinguishing mechanism. In the centre of the burner of each lamp is a small ring of fine platinum wire, which is so contrived as to touch the wick of the lamp, and the current of electricity being made to pass through this platinum ring, it becomes intensely heated, and thereby ignites the wick of the lamp. I do not restrict myself, however, to the employment of platinum wire, as carbon for this purpose may be used, or any other difficultly fusible material; neither do I limit myself to the employment of a ring of any particular form. The wick may, for instance, be a flat wick, and in that case a straight piece of wire would be suitable for the arrangement.

How the wires from the battery are connected in the last arrangement with the lamps and the escapement, Mr. Staite considers it unnecessary to describe, "as the mode of doing so must be obvious to all who are familiar with the subject of electricity." "It may be sufficient," he adds, "to state, that one wire for the return current will be sufficient for the whole series of lamps and the mechanism connected therewith."

STUDENTS' COLUMNS.

CITY AND GUILDS EXAMINATIONS.

[*These answers are intended to guide, to give information and references, to put the student in the way of getting information, and* NOT *to give the exact answers that should be written in an examination.*]

The solutions in this number are alternative solutions to some of the earlier questions in the paper hitherto considered, by E. C. RIMINGTON, ESQ. (School of Electrical Engineering), 12, Princes-street, Regent-street.

1. Explain fully why, at the present day, it is more economical to light large rooms with the electric light than with gas, and why this was not the case some few years back.

Ans. For lighting large rooms we can employ arc lamps, from which we can obtain, as an average, 1,500 candle-power per h.-p. indicated.

Now, in the average engines, one h.-p. can be obtained by the consumption of 2½lb. of coal per hour, and, in some of the more improved ones, of less than 2lb. An ordinary gas burner, with the best gas, gives a light of 30 candles per 5 cubic feet consumed per hour. About 11·3 cubic feet of gas are obtained from the destructive distillation of 2½lb. of coal. Therefore, 1,500 candle-power require 4·42lb. of coal in the shape of gas, which makes the electric light for large rooms nearly half the price of gas as regards the quantity of coal consumed.

Even in using the incandescent system as at present, where the average candle-power is only about 300 per h.-p., we must remember that the air is not contaminated by the products of combustion as in the case of gas; there also being no smoke, there will be consequently a great saving of whitewash. In libraries it will be specially useful, as it is an undisputed fact that gas destroys the backs and covers of all leather-bound books exposed to its influence.

3. Explain fully, with sketches, how dynamo machines of the Brush type differ from those of the Gramme? What are the relative advantages and disadvantages of direct and alternate current dynamos?

Ans. As regards the internal arrangement, in the Gramme dynamo no coils are cut out at any period of the revolution, but the current flows through all of them, while in the Brush machine each pair of coils, as it passes the neutral point of the field, and is therefore incapable of doing work, is cut out of the circuit.

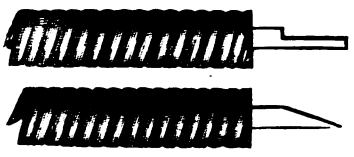
The advantage of an alternating current dynamo compared with a direct current dynamo is that in the former no commutator is required, which renders the construction of the machine much simpler, its disadvantage being that the iron, if any, forming the cores of the field magnets is more liable to become heated through its rapid magnetisation and demagnetisation. An alternating current machine has also the disadvantage that it cannot be employed to charge accumulators, as in the case of a direct current machine. It is said, however, that incandescent lamps

Digitized by Google

lighted by an alternating current, have a longer life than when a direct current is employed to illuminate them.

4. A joint has to be made between the ends of two thick electric light wires. Explain, and give sketches of, the method of jointing you would employ. In carrying wires, between which there is an electromotive force of 300 volts, through the rooms of a building, what method of insulation would you make use of? Show exactly how you would lead wires to a number of incandescent lamps suspended from a bronze chandelier, and give the reasons for adopting your method.

Ans. Strip the ends of the cables to be joined for two or three inches, solder together the separate strands into a solid mass capable of being easily filed, file the ends of each to one of the accompanying forms. Fit them together, bind with a piece of fine wire, say No. 26 B.W.G.; run solder into the joint thus formed, finally insulate the joint with some insulating compound, and wrap round with tarred tape. In carrying wires having an E.M.F. of 300 volts between them they should, where it is possible, be carried along on opposite walls of the rooms. If this is impracticable they should be run at a distance of, at least, 12 inches from one another; and, if at any point it is absolutely necessary to cross the wires, one of them should have a piece of wood, cut with a notch to receive the wire, fastened over it, and the other laid over the top of this piece of wood. The wires should themselves be well insulated with tarred tape or other insulating compound. Wires insulated with a mixture of paraffin and colophane or resin, and then encased in a piping of lead, as manufactured by MM. Berthoud and Borel, are exceedingly useful for this kind of work. The suggestion given by Mr. Massey, of the Electric Light and Power Generator Company, that the leading should be placed to the left or lower, and the return wire to the right or higher, might also be advantageously followed.



In leading wires to a number of incandescent lamps suspended from a bronze chandelier, one of the terminals of each lamp should be connected to the chandelier; the other to a well-insulated wire, the wires being run through the stem of the chandelier.

A few notes on some of the questions may guide students where to look for information.

Question 11 deals with photometry, an important but little studied subject. Brief accounts will be found in Watt's "Dict. of Chemistry," vol. iii., p. 597, in "Deschanel," 6th edition, p. 963, in Thresh's "Physics," p. 161, in Ganot's "Physics," &c., in fact, the ordinary methods are to be found in almost any book on Light, or Physics. Specific information, however, is perhaps only to be obtained from various papers by Professor Tyndall, Professor Ayrton, Dr. Siemens, Mr. Sugg, &c. The greatest mistake students make is to rely upon text books for information. The text book must, as a rule, be a year or two—it may be, more—behind the times, and it is only by constant reading of technical journals and the *Proceedings* of learned societies that one can hope to keep abreast with progress.

Question 14, referring to the transmission of power by electricity, is a case to the point. So far as we know, only one book has been published which deals with this question, that of Dr. Paget Higgs, issued by Messrs. Spon in 1879. But a good deal of attention has been given to the subject since 1879, and it is just now attracting more attention than ever. We think we are justified in saying that students should study this subject, as presenting one of the greatest fields for original investigation. Besides our own paper, we would refer to *La Lumière Electrique*, *Comptes Rendus*, the various papers of M. Deprez, and his critics. We plead ignorance of Frölich's work, which, as yet, has not an English dress, though we may mention here that Schellen's "Magnet und Dynamo-Electrischen Maschinen" is about to be published by Messrs. Van Nostrand and Co. in America.

To be Wound Up.—A petition for winding up the Phœnix Electric Light and Power Company has been presented to the High Court of Justice.

CORRESPONDENCE.

STATIC ELECTRICITY.

TO THE EDITOR OF THE ELECTRICIAN.

Sir: In an article entitled "The Inductive and Conductive Circuits," at page 128 of this volume, Mr. J. T. Sprague begins with the extraordinary assertion—there is no such thing as a *quantity of static electricity*. The first reason which he gives for making this statement is that the practical unit of electrical quantity, the coulomb, is independent of the actual nature of electricity, and is simply measured by certain results of electrical action. His second reason is exactly of the same kind, for here he maintains that "that quantity of electricity which, placed at unit distance from an equal similar quantity, repels it with unit force, is not a quantity of electricity, but of force."

In both cases he loses sight of the distinction between a quantity and the measurement of that quantity.

For example, the unit of force is defined to be the force which produces unit of momentum in unit of time. Will Mr. Sprague, therefore, assert that there is no such thing as a quantity of force?

Mr. Sprague finally explains that by static electricity he means potential energy, and by dynamic electricity he means kinetic energy, and by combining this with Mr. Sprague's statement that there is no such thing as a quantity of static electricity, the result obtained is there is no such thing as a quantity of potential energy, but that quantity of energy can only have a meaning in the case of kinetic energy. With regard to any statement which would require electricity to be a form of energy, I must remind Mr. Sprague that if in any given time a quantity, Q, of electricity pass through a linear conductor along which a constant electromotive force, E, is acting in the direction of flow, the work W done in the given time will be E Q.

Thus the amount of energy expended is E Q, and as E is not a quantity of zero dimensions, or mere number independent of the units employed, it follows that Q or $\frac{W}{E}$ cannot possibly be an expression for energy.—Yours, &c.,

G. W. Von Tunzelmann.

"GLOW" LAMPS.

TO THE EDITOR OF THE ELECTRICIAN.

Sir: Dr. Siemens in a recent lecture suggested the term "glow" lamp in preference to "incandescence" lamp; and I observe that Mr. Preece has accepted the innovation, which, he states in a recent lecture to the Society of Arts, to be equally correct and more euphonious than "incandescence," while being also more in accordance with the spirit of the age. The present tendency is certainly towards brevity of expression in English; but accuracy ought not to be sacrificed to mere brevity, and, with due deference to Mr. Preece, I think it can be shown that "glow" is not so correct as "incandescence." A glow can be produced in a variety of ways, but incandescence only in one way. We have the glow of burning phosphorus, of luminous paint, of the *glow*-worm spark, of the aurora, of the "gloaming" sky, of the Alpine heights after the sun has set (the after-glow); but incandescence is only produced by heating up a solid body until it emits light. To give out white light, its temperature ought, as is well-known, to be roughly 1,000° F. Therefore, the carbon filament lamp is very properly an "incandescence," and less properly a "glow" lamp.—Yours, &c.,

J. Munro.

2, Somerset-villas, West Croydon, December 27.

CROMPTON'S COMPOUND MACHINE.

TO THE EDITOR OF THE ELECTRICIAN.

Sir: I can hardly be expected to answer the vigorous, not to say violent, personal attack contained in one of the letters

Digitized by Google

on this subject you published in your last issue, for such correspondence, besides being uninteresting to the public, is always undignified, and particularly so when by a slight admixture of technical matters it manages to creep into the columns of a high-class scientific journal. By the tone of the letters one might be led to believe that not only was compounding an old idea (which I never denied), but also that compound machines have been a regular article in the market since the spring of 1881. As it would be very interesting to have this point cleared up, will you or any of your readers kindly state where compound machines of other than Messrs. Crompton's manufacture, and of previous make, can be seen at work in England?—Yours, &c.,

Chelmsford, December 27, 1882. GISBERT KAPP.

SECONDARY BATTERIES.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In reply to your correspondent, Mr. B. Unwin, I am happy to supply any particulars relating to the application of secondary batteries to arc lighting.

The Sellon-Volckmar accumulators which were shown at my lecture at Limehouse were of the one horse-power type, capable of furnishing a current of 20 amperes for 15 hours, or 30 amperes for 10 hours; in other words, their capabilities may be expressed by 300 amperes-hours.

Since this accumulator adapts itself to any requirements for high or low currents, it is necessary that the circuit should be properly arranged.

An arc lamp, to work with accumulators, must be accurately adjusted, the carbons must be fed gradually, and not by sudden jerks.

The accumulator in question is capable of giving a current of over 100 amperes for a short time, and this current would work great mischief in some lamp-fittings if allowed to flow at that rate; thus, if the carbon-rods were to touch each other, there would be a tendency for the current to make the carbons incandescent throughout their whole length, and the result would be a rapid discharge of the accumulators, and great diminution of light.

Until a new arc lamp is devised in which the carbons are prevented from touching each other, it will be necessary to insert such a resistance in circuit as will prevent a too powerful flow of current, and this latter method I adopted with the Pilsen lamp, which gave a perfectly steady light with 10 amperes and 56 volts.—Yours, &c.,

A. RECKENZAUN.

Poplar, December 27, 1882.

THE AURORA.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I read your amusing editorial on the 8 h.-p. electric light at Milwaukee, illuminated by the aurora.

The facts were simply that an Edison incandescent lamp was attached to one of the St. Paul, Western Union, Telegraph wires, with the other side to earth. It is an 8-candle lamp, requiring about $\frac{1}{8}$ h.-p. to illuminate it, not 8 h.-p. The auroral current developed about half the capacity of the lamp, using probably $\frac{1}{16}$ h.-p.

The agent of the Associated Press was unduly excited at New York, and so it went through the cable to your papers as 8 h.-p.—another illustration of the depth of scientific knowledge possessed by newspaper men.—Yours, &c.,

C. H. HASKINS.

IS THE MICROPHONIC CONTACT AN "ARC?"

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I committed an error in my last letter in saying electromotive force of "2 volts of a Leclanché cell." This, of course, should be 1·4.—Yours, &c., E. BERLINER.

The American Bell Telephone Company, 95, Milk-street, Boston, U.S.A., Dec. 9.

ELECTRIC REPULSION—III.

BY J. T. SPRAGUE.

In two previous papers I have shown that apparent repulsions belong to two orders of cause: 1, to the transfer of motion from one body to another; 2, to the sum of the actions of a "field of force." This latter process is so readily traceable in the mutual action of magnets, that it seems preferable to study the action there rather than in the electric field of force, which is by no means so easy to trace out. The appearance of an active repulsive force is also more strong in the case of magnetism than in any other, because not only is there no attraction between like magnetic poles, unless one is strong enough to overpower the other, but they do seek to avoid each other, and no apparent source of attraction exists in the opposite direction. If, therefore, repulsion and repulsive force are negatived in the case of magnetism, the argument in favour of their existence is greatly weakened. This having been accomplished, it is a simple matter to deal with electric repulsion proper.

Two bodies *similarly electrified repel each other.*

When two pith balls hanging side by side are electrified from the same source, they separate, and appear disinclined to come together.

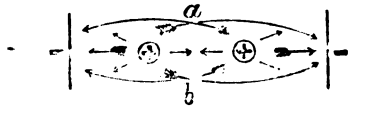
When an electric is rubbed it attracts light bodies, and then repels them.

Let us examine the last statement first; and, first, let us inquire, although it is found in all the text books, *is it true?* A quarter of an hour ago I took a rod of ebonite eighteen inches long (and the length is important); I rubbed its end on my coat, held it towards a small piece of light paper very thoroughly dried, and instantly stood the rod upon a holder a good distance from other bodies; that paper is still adhering to the rod upon its lower face, held up by attraction. I now brush it off on the table, excite my rod again, and hold it quietly just over the paper. This springs to the rod, flutters about between it and the table several times; then it stands on edge, and follows small motions of the rod; then appears to prefer to cling edgeways to the rod rather than the table, and at last lies down and clings to the rod.

I now make one of the prettiest repulsion experiments I know of. Instead of paper, I lay on the table a small piece—about ¼ of an inch square—of light gold leaf. I attract it with the excited rod, and then shake it off into the air. This requires careful management; the attraction must be from a distance, and the leaf will not abandon the rod very readily, or till the excitement has lowered; but, once in the air, the leaf may be guided at pleasure with the rod. It will not allow an approach. In this manner I drive the leaf over a gas-flame, so that the heated air rushes it up against the ceiling, whence it falls discharged. It can be caught again on the rod, which now attracts it, and the process repeated without freshly exciting the ebonite.

This is not repulsion, however, for the leaf will not readily leave the rod. It is a clear case of suspension and motion in a "field of force." The excited electric forms one electrode, and sets up a circuit through the body of the operator to the floor and the walls and ceilings, over which there is spread, in small density, the + charge corresponding to the dense — charge developed on the ebonite; from the ebonite lines of force or electric tension radiate to the walls. But while the leaf was on the rod it formed part of the — electrode, and remains, when separated, a distinct centre of a second field of force. Now, wherever the rod is placed these two fields interfere between the leaf and one surface; if it is placed below, the attraction from the floor is neutralised; the lines of force in that direction close on the rod, then the tension in the lines of force from the ceiling acts as an attractive force upwards, and the leaf rises. This occurs because the effect of its rising is to shorten the field of force centering on the leaf; the leaf, though rising against gravitation, is really running down hill electrically.

The same principles govern the motion of the two balls suspended side by side, or the gold leaves of the eletroscope. The diagram will explain this:



+ + are the two charged balls, and — — are the surrounding surfaces, to which proceed lines of force, developing attractions in the direction of the arrows. It is evident that the space enclosed between + and + and outwards towards *a* and *b* is a neutral field in which the opposing forces are indicated by the opposite arrows. There is, therefore, no attraction in this direc-

Digitized by Google

tion to counterbalance that acting in the direction of the nearest —. It will be seen, therefore, that one + fulfils the functions of the excited rod in the floating leaf experiment, while the other + represents the leaf itself.

The idea of a repellent force naturally occurred to the early experimenters, who imagined that electricity was a something which could be isolated and placed upon a *single* surface; it is entirely out of place in any system which recognises the dual nature of electricity, and that it is just as impossible to have an isolated + or — charge of electricity as it is to have an isolated north or south pole of magnetism.

SCREW GAUGES.*

1. This committee was formed by the General Committee of the British Association assembled at York in August and September, 1881, for the purpose of determining a gauge for the manufacture of the various small screws used in Telegraphic and Electrical Apparatus, in Clockwork, and for other analogous purposes.

2. At that meeting a paper was read by Mr. Preece pointing out the desirability of establishing such a gauge. Although the Whitworth gauge is almost invariably adopted for the bolts and screws used in mill-work and engineering in England, no general system has been hitherto applied to the smaller screws used either in clockwork, philosophical instrument work, or in the numerous practical applications of electricity that are now rapidly becoming so important. In fact, at the present time gauges and screw plates almost equal in number the makers engaged in the trade. One instance was brought to the attention of the committee by a manufacturer who had to execute an order for railway signal apparatus in accordance with three sample instruments containing among them twenty-one screws of different threads, not one of which happened to be in use in his shop. There is now no recognised form of thread, no specified number of threads per inch—in fact, no generally accepted gauge based on practice and experience. Great inconvenience is felt in providing for repairs, which are, in consequence, more costly and less efficient.

The employment of some coherent and uniform system is manifestly required. It not only would render repairs easier, speedier, and cheaper, but it would introduce interchangeability of parts, and further the extension of piece-work; and it would reduce the equipment of workshops with special and costly tools.

3. The subject of uniformity in screws has been very warmly taken up by the Société des Arts de Genève, which appointed a committee in December, 1876, who, after assiduous labours, issued a report in 1878. The system proposed by them has been very fully described by Professor Thury in two pamphlets published in Geneva.† The committee collected numerous screws of all sizes from many factories, measured them carefully, tabulated their several dimensions, and plotted the results by the ordinary method of linear co-ordinates. They determined the mathematical equations to curves that most closely corresponded with the ratios of diameter to pitch thus found to have been employed in practice, and adopted the one which most nearly represented the mean average proportions of the screws in use at various shops and in different countries.

The Swiss Committee took 1 millimetre pitch as the basis of their system. It was agreed that such a pitch was best adopted to a screw having a diameter of 6 millimetres. The form of thread adopted was triangular, the angle made by producing the two sides being approximately 47½deg.; the depth being $\frac{3}{5}$ of the pitch, the top being rounded off by a radius $\frac{1}{6}$ and the bottom by a radius $\frac{1}{5}$ of the pitch.

The committee has had an opportunity of examining screw plates and numerous packets of the corresponding screws manufactured on the system.

The following table gives the pitches and diameters in millimetres and "mils ‡" to two significant figures, and the number of threads per inch of all the screws comprised in the small screw series, which happens to cover the exact ground to which the attention of the committee has been specially directed, namely, diameters below the ¼in.

Table of Swiss Screws.

No.	Pitch.		Diameter.		Threads per inch.
	Mm.	Mil.	Mm.	Mil.	
25	0·072	2·8	0·25	10	357
24	0·080	3·1	0·29	11	323
23	0·089	3·5	0·33	13	286
22	0·098	3·9	0·37	15	256
21	0·11	4·3	0·42	17	233
20	0·12	4·8	0·48	19	208
19	0·14	5·3	0·54	21	189
18	0·15	5·9	0·62	24	170
17	0·17	6·6	0·70	28	152
16	0·19	7·3	0·79	31	137
15	0·21	8·1	0·90	35	124
14	0·23	9·0	1·00	40	111
13	0·25	10·0	1·2	46	100
12	0·28	11·	1·3	52	91
11	0·31	12·	1·5	59	83
10	0·35	14·	1·7	67	71·4
9	0·39	15·	1·9	76	66·7
8	0·43	17·	2·2	86	58·8
7	0·48	19·	2·5	97	52·6
6	0·53	21·	2·8	111	47·6
5	0·59	23·	3·2	126	43·5
4	0·66	26·	3·6	142	38·5
3	0·73	29·	4·1	162	34·5
2	0·81	32·	4·7	183	31·2
1	0·90	35·	5·4	208	28·6
0	1·00	39·	6·0	236	25·6

It is to be observed that the numbers by which the screws are designated, given in the first column, are not arbitrary. Each pitch of the series is $\frac{9}{10}$ths of that which succeeds it in the table

Thus, the several pitches are:—

$$1 \text{ mm.}; \frac{9}{10} \text{ mm.}; \left(\frac{9}{10}\right)^2 \text{ mm.}; \left(\frac{9}{10}\right)^3 \text{ mm.}; \ldots \left(\frac{9}{10}\right)^n \text{ mm.}$$

This series may be expressed in the form:—

$$0{\cdot}9^0; 0{\cdot}9^1; 0{\cdot}9^2; 0{\cdot}9^3; \ldots 0{\cdot}9^n; \ldots \quad (1),$$

whence it is at once evident that the designating number of a screw is the index of the power to which 0·9 must be raised in order to ascertain its exact pitch in millimetres.

The method by which the relation between pitch and diameter is arrived at will be gathered from the following explanation:—

Let D represent the diameter and P the pitch. Then, generally,

$$D = f(P).$$

Evidently there can be no constant term, for when D = O, P must also = O. Moreover, D practically cannot be a simple multple of P, for experience has shown that small screws must have a less number of threads per diameter than large screws.

Hence the formula will be of the form

$$D = m P^k \quad \ldots \ldots \quad (2),$$

where m and k are constants to be determined.

Since 1^k is 1 whatever be the value of k, it follows that the coefficient m represents the value of D when P is 1. The Swiss Committee agreed that the unit pitch (1 millimetre) should be adopted for the screw having a diameter of 6 millimetres; in other words they make $m = 6$.

The value of k must be ascertained by trial.

$k = 1$ would give a constant ratio, which we know is inadmissable.

$k = 2$ will be found on trial to give a far too rapid decrease in the ratio of diameter to pitch.

The several simple fractions between these limiting values were tried in succession, and the results obtained when using $\frac{6}{5}$ were found to give results that best accord with practice and experience.

Substituting the values thus arrived at in (2), the formula becomes

$$D = 6 P^{\frac{6}{5}} \quad \ldots \ldots \quad (3).$$

The Swiss system is thus very complete, but there are reasons which prevent this Committee from recommending its adoption in its entiety.

4. No one has done more to establish gauges of all kinds in England than Sir Joseph Whitworth. His classical paper on "An Uniform System of Screw Threads" was communicated as

* Report of the British Association Committee, consisting of Sir Joseph Whitworth, Dr. Siemens, Sir F. J. Bramwell, Mr. A. Stroh, Mr. Beck, Mr. W. H. Preece, Mr. E. Crompton, Mr. E. Rigg, Mr. A. Le Neve Foster, Mr. Latimer Clark, Mr. Buckney, and Mr. H. Trueman Wood (secretary), appointed for the purpose of determining a gauge for the manufacture of the various small screws used in telegraphic and electrical apparatus, in clockwork, and for other analogous purposes.

† *Systématique des vis Horlogères*, Geneva, 1878. *Notice sur le Système des vis de la Filière Suisse*, Geneva, 1880.

‡ The "mil" is the thousandth part of the British inch.

Digitized by Google

far back as 1841 to the Institution of Civil Engineers. He had made an extensive collection of screw-bolts from the principal workshops throughout England, and the average thread was carefully measured for different diameters. The ¼, ½, 1, and 1½ inch were selected and taken as the fixed points of a scale by which the intermediate sizes were regulated. The result is an admirable thread for the large iron bolts and screws used in fitting up steam engines and other machinery. The angle made by the sides of this thread is 55deg. One-sixth of the depth of the thread is rounded off from the top, and one-sixth from the bottom. The actual depth is rather more than three-fifths, and less than two-thirds of the pitch.

The slow adoption of such an admirable system was perhaps due, in great measure, to the fact that it was put forward by an individual and not by an association. A single individual, however exalted his reputation, cannot secure that immediate and universal attention which is obtained by such an organisation as the British Association. The system of units of electrical measurements sanctioned by the association obtained instant recognition, and has now, thanks to the Congress of Electricians held in Paris in October, 1881, become universally accepted. It is hoped that the same result will follow the recommendations of this committee.

5. The question of the introduction of the metrical system occupied the serious consideration of the Committee, but, considering the fact that it is not generally adopted in engineering or manufacture in England, and that it is as yet little understood by our workmen, it was thought better to suggest no change in this direction. The Committee is not insensible to the simplicity of the metrical system and to its possible universality, nor to the fact of its gradual introduction in scientific circles, but while the manufacturing interests are still wedded to the British inch and its multiples and sub-multiples, and while the British legal standard of length is still the yard, the Committee has felt it impossible to suggest a change which has little chance of adoption, and which might jeopardise the introduction of that with which they are more concerned—viz., a uniform screw-thread.

Hence it was determined that the unit of length taken should be the "mil," and that the decimal system should be adopted for expressing dimensions.

6. The use of a screw is to draw together and to unite certain parts of apparatus in firm and intimate contact. To attain these ends a screw must facilitate the application of mechanical power to draw the parts together, and it must possess strength to hold them so; it must not interfere with the easy separation of these united parts when necessary; it must possess durability—that is, it must be capable of repeated use without undue friction and without wear, otherwise it will speedily become loose and dangerous when frequently removed and restored. There has to be considered the pitch of the screw, its relation to the diameter of the bolt on which it is cut, the depth of the cut, and the form of the thread. The pitch primarily determines the power of the screw, for it determines, for each diameter, the angle of the inclined plane; the depth determines the section of core left to resist shear or rupture; while the form of the thread determines the durability and efficiency, and determines also the surface of thread to bear endway strain.

7. The Committee have devoted very considerable attention to the pitch, form, and depth of screws, and they have compared together a large number of different kinds, some of which are in actual use, while others have only been suggested. They have, moreover, decided on recommending the adoption of the Whitworth form of thread, not only because it is so well known, but because experience has proved it excellent and unsurpassed when employed for engineers' bolts. The Committee, however, are not unanimous on all questions involved by this proposal, and as there are several points that require to be thoroughly sifted and tested, they ask to be reconstituted and to be allowed a small grant to put their proposal to the test of practice, and to have a few gauges constructed for distribution or examination.

DETECTION OF METALLIC MASSES IN THE HUMAN BODY.*

BY ALEXANDER GRAHAM BELL.

(CONTINUED FROM PAGE 140.)

Continuing the experiment, the coil B was moved a determined distance beyond the plane of A, and the balancing coils again adjusted to silence. The brass ring C was once more caused to disturb the balance, and the new hearing distance was noted. The following are the tabulated results of a series of experiments made on the 19th July, 1881. The battery employed consisted of six bichromate cells connected in series:—

Diameter of Primary Ring.	Distance between—			Diameter of Primary Ring.	Distance between—		
	A B.	B C.	A C.		A B.	B C.	A C.
mm.	mm.	mm.	mm.	mm.	mm.	mm.	mm.
	0	17	17		0	27	27
	5	14	19		5	20	25
30	10	13	23	159	10	18	28
	20	9	29		20	17	37
	30	7	37		30	14	44
	50	0	50		50	14	64
	0	17	17		0	12	12
	5	19	24		5	18	23
50	10	26	36	206	10	25	35
	20	17	37		20	19	39
	30	14	44		30	22	52
	50	5	55		50	18	68
	0	21	21		0	20	20
	5	23	28		5	18	23
81	10	23	33	253	10	20	30
	20	18	38		20	19	39
	30	14	44		30	23	53
	50	12	62		50	20	70
	0	22	22				
	5	25	30				
113	10	27	37				
	20	26	46				
	30	26	56				
	50	17	67				

These figures show that *the distance from the primary coil* A (Fig. 8) *at which the influence of the brass ring* C *became perceptible increased with the diameter of the primary ring, and that the secondary coil* B *required to be projected considerably beyond the plane of the primary in order to obtain the maximum effect.*

The conclusion seemed a natural one that the degree of projection A B of the secondary coil should proportionally increase with the diameter of the primary ring, but the tabulated figures did not fully justify the inference.

The experiments had necessarily occupied a considerable time, and I thought that the difference between the results that should have been observed, according to the above hypothesis, and those that were actually obtained, might have been due to the gradual exhaustion of the bichromate battery employed and to its polarisation, although every care had been taken to preserve its power by removing the carbon and zinc plates from the solution, excepting when an observation was made. To test whether the battery exerted any material influence upon the hearing distance, a further series of experiments was made with the same battery.

It will be seen by reference to the tabulated statement shown above that the maximum hearing distance B C had been obtained with a primary ring 11·3cm. in diameter when the distance A B between the primary and secondary coils was one centimetre. This arrangement of the apparatus was, therefore, adopted throughout the following experiments:—

	Hearing distance.
1. Apparatus tried with 1 cell (bichromate battery) (B C, Fig. 8)	= 9 mm.
2. Six cells in series (B C, Fig. 8)	= 16 mm.
3. Six cells in multiple arc (B C, Fig. 8)	= 9 mm.
4. Six cells in two series of 3 each (B C, Fig. 8)	= 15 mm.
5. Same experiment repeated (B C, Fig. 8)	= 13·5mm.
6. Same experiment repeated by Mr. Tainter (B C, Fig. 8)	= 12·5mm.

These experiments proved that the battery power *did* exert an influence upon hearing distance, and also that the battery in use was gradually deteriorating.

I concluded, therefore, that if the battery power had remained constant, the hearing distance might not only have been proportional to the diameter

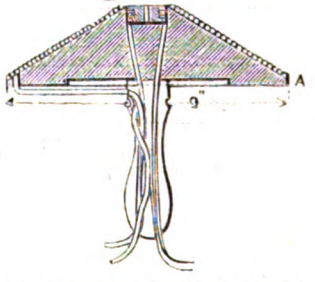


FIG. 9.—(Secondary Coil, 1 inch.)

of the primary ring, but, in order to attain the maximum effect, the projection of the secondary coil beyond the plane of the primary might also have been found to increase in like proportion.

This led me to try the effect of a conical primary coil, A, with the secondary, B, at its apex, as shown in Fig. 9, but the hearing distance for a bullet was only 3·5 cm.

Singularly enough, Mr. J. H. C. Watts, in Baltimore, had independently arrived at a very similar form of coil, and with the instrument shown in

* A Paper read before the American Association for the Advancement of Science at the Montreal Meeting, August, 1882.

Digitized by Google

Fig. 10 he had obtained at one time a hearing distance of 7·5 cm. (or 3in.*), but from some cause not ascertained he was unable subsequently to reproduce the effect.

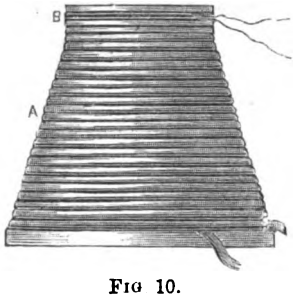

FIG 10.

The final form of apparatus adopted as the result of the above experiments is shown in Fig. 11. With this arrangement and a battery of six bichromate elements freshly set up, we were always sure of a hearing dis-

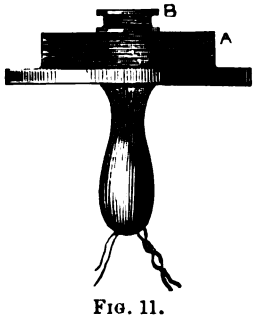

FIG. 11.

tance of at least 5 cm., although after the battery had been in use for some time the hearing distance hardly exceeded 4 cm.

The following are the dimensions of the coils A B (Fig. 11) and their resistance :—

COIL A.....	External diameter	7 cm.
	Internal diameter	4·5 cm.
	Depth	2·4 cm.
Wire used, No. 23 (cotton covered). Resistance, 2 ohms.		
COIL B.....	External diameter	2·3 cm.
	Internal diameter	8 mm.
	Depth	8 mm.
Wire used, No. 36 (silk covered). Resistance, 75 ohms.		

The face of the coil B projected beyond the face of coil A 4 mm.

The balancing coils were made as nearly as possible the duplicates of A and B. The resistance of the coil of the telephone employed was 75 ohms.

Influence of Battery Power.

The following experiments were made with this apparatus (Fig. 11) on July 20, 1881, to test the influence of battery arrangements upon the hearing distance of a leaden bullet.

I. *Series of experiments with a bichromate battery which had previously been in use for a few minutes.*

	Hearing distance of leaden bullet as observed by	
	A. G. Bell.	S. Tainter.
	cm.	cm.
1 cell.....	2·4	2·6
2 cells in series	3·3	3·5
3 cells in series	3·7	4·1
4 cells in series	3·7	4·0
5 cells in series	4·0	4·1
6 cells in series	4·3	4·4
6 cells in multiple are	2·6	2·9
6 cells in two series of 3 each	3·8	3·7
6 cells in three series of 2 each ...	4·3	4·0

II. *Series of experiments with a Leclanché battery of twenty cells which had been set up for about one month. It had been kept normally upon open circuit, and had only been occasionally used.*

	Hearing distance.
20 cells in series.....	3·3 cm.
20 cells in 10 series of 2 each	3·6 cm.
20 cells in 5 series of 4 each	4·1 cm.
20 cells in 2 series of 10 each	3·0 cm.

Although the battery appeared to be in good condition, a close inspection showed that the connections were dirty, and that one of the zinc wires was half broken through.

* See Appendix, note 11.

The defective cell was now removed from the circuit, and the connections of all the other cells cleaned and tightened.

III. *The following experiments were then made with the Leclanché cells united in series:*

No. of cells.	Hearing distance.	No. of cells.	Hearing distance.
	cm.		cm.
1	2·7	11	3·8*
2	2·8	12	4·2
3	3·0	13	4·2
4	3·3	14	4·2
5	3·3	15	4·3
6	3·5	16	4·2
7	3·6	17	4·2
8	3·8	18	4·2
9	4·0	19	4·2
10	3·8*		

These results are graphically represented in Fig. 12.

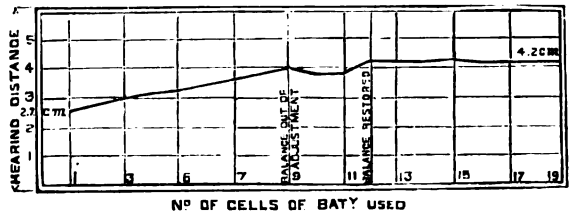

FIG. 12.

It will be observed that the hearing distance was carried nearly one-third as far again as at first, simply by increasing the number of cells employed without any other change in the arrangement. It will also be noticed that the apparatus requires to be adjusted to complete silence in order to obtain the maximum effect.

As a general result of all our experiments with voltaic batteries, we find that *it is advisable to use a battery possessing great electromotive force and slight internal resistance, and to connect the cells in series.*

Experiments upon Living Subjects.

On the 22nd of July an experiment was made at the request of Dr. Bliss upon the person of Lieutenant Simpson, who had carried a bullet in his body for many years.

When the exploring instrument (Fig. 11) was passed over the lieutenant's back a sonorous spot was found, but the indications were too feeble to be implicitly relied upon. Imagination very easily conjures up a feeble sound like that observed, but a number of experiments by different observers seemed to indicate that in this case there was an external cause for the sound—probably the presence of a very deeply-seated bullet. The results of this experiment were communicated to Dr. Bliss in a letter dated July 23rd, 1881.†

On the 25th of July Professor Rowland visited me at Washington, and suggested the use of a condenser in the primary circuit. I had previously discussed this idea with Mr. Tainter, but, not having a condenser at hand, we had been unable to make any experiment. After our conversation with Professor Rowland, however, we were so impressed by the importance of the point that we obtained a condenser next morning, and found it to produce not only a different quality of sound when the bullet approached the coils, but also to increase the hearing distance of the instrument shown in Fig. 11 at least one centimetre.

On the evening of the same day (July 26th) our apparatus was carried to the executive mansion, and an experiment made upon the person of the President.‡

From some cause then unknown a balance could not be obtained, and the results were therefore uncertain and indefinite. It was discovered afterwards that a mistake had been made in the mode of connecting the con-

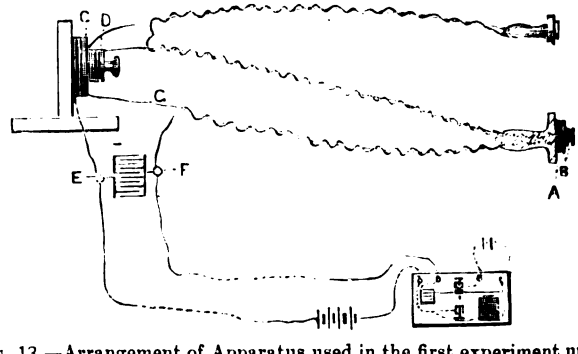

FIG. 13.—Arrangement of Apparatus used in the first experiment upon the late President Garfield, July 26, 1881.

denser. The latter should have been connected at E F (Fig. 13), whereas it was placed at E G, thus influencing only one, instead of both, of the primary coils.

With the condenser properly arranged experiments were tried on July 29

* Balance not quite perfect. † See Appendix, note 12. ‡ See Appendix, note 13.

Digitized by Google

and 30 on three soldiers from the Soldiers' Home who had been wounded during the civil war, namely, John Teahan, Asa Head, and John M'Gill.

In the case of John Teahan no results were obtained. In the case of Asa Head, who had a buckshot in the cheek, loud and well-marked sounds were heard in the telephone; and in the case of John M'Gill, who was supposed to carry a bullet in his back, no results were obtained.

Further efforts were then prosecuted for the improvement of the apparatus.

Further Experiments to Improve Apparatus.

Our attention had hitherto been directed chiefly to modifications of the exploring instrument. We now investigated the effect, upon the hearing distance, of the coils used to obtain a balance.

The following experiments, made July 29, 1881, bear upon the point: –

Exp. 1. (See Fig. 14.) Resistance of primary A of exploring instrument, 2 ohms; resistance of primary C of balancing coils, also 2 ohms; resistance of exploring secondary B, 140 ohms; and of balancing secondary D, 120 ohms.

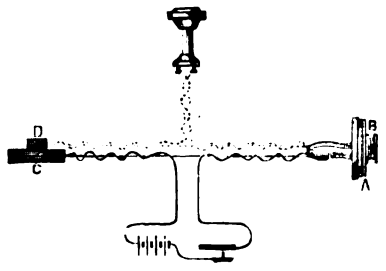

Fig. 14.

Result: Hearing distance of bullet from explorer A B, 3·5 cm. Hearing distance from balancing coils C D, also 3·5 cm.

Exp. 2. (See Fig 15.) Same exploring coils as in Exp. 1, but balancing coils consisted of a flat primary, E—resistance, 5·30 ohms; and flat secondary, F—resistance, 83 ohms. The adjustment was made by sliding the secondary coil upon the primary until a position of silence was obtained.

Result: Hearing distance from explorer A B, 1·5 cm. Hearing distance from E F, 3 cm.

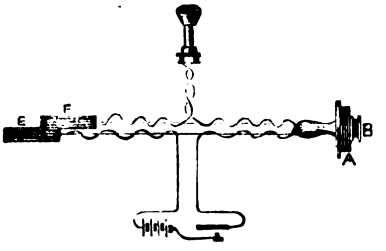

Fig. 15.

As a general result of our experiments we found that *every increase in the resistance of the balancing coils (especially the primary) reduced the hearing distance of the exploring instrument*, and it became therefore desirable to do away with this source of resistance as much as possible.

Return to Original Form of Apparatus.

This led us back to the original form of apparatus that had first occurred to me (see Fig. 1), in which a single pair of coils was employed. A few other experiments, made July 29, 1881, will show the importance of the point attained.

Exp. 3. The two flat coils E F used in Experiment 2 were arranged as in Fig. 16, so as to form a balance by themselves.

Result: Hearing distance, 7 cm.

In all these experiments the battery used consisted of four cells (Leclanché).

Fig. 16.

Exp. 4. The same coils used in Exp. 3 were tried again, as shown in Fig. 16, but with a battery of eight cells (Leclanché).

Result: Hearing distance, 8·7 cm., or nearly 3½in.—a result quite unprecedented in our experiments.

The following are the dimensions of the coils E F:—

Coil E.....	External diameter	10 cm.
	Internal diameter	2·5 cm.
	Depth.....	1 cm.
	Wire used, No. 23 (silk covered).	
Coil F.....	External diameter	10 cm.
	Internal diameter	2·5 cm.
	Depth.....	1 cm.
	Wire used, No. 28 (silk covered).	

Exp. 5. The same coils, E F, used in Exps. 2, 3, and 4, were tried once more with a battery of six large bichromate elements, and with a condenser, G, in the primary circuit as shown in Fig. 17.

Result: Hearing distance 13cm., or more than 5in.

This great increase in hearing distance seemed to be chiefly due to the condenser, for upon disconnecting it the hearing distance was little more than 9cm., but further experiments proved that other causes also contributed to the result.

Exp. 6. When the condenser was in circuit and the leaden bullet close to the coils (arranged as in Fig. 17) the sound produced by the telephone was a musical note whose pitch was the same as that normally produced by the vibration of the reed of the interrupter. Mingled with this tone could be distinguished a number of feebler tones of very much higher pitch. Upon withdrawing the bullet gradually from the coils the fundamental sound became fainter, and one of the high upper-partial tones gradually acquired

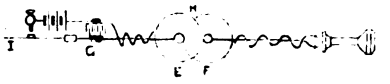

Fig. 17.

prominence; and at a distance of about 8 or 9cm. the fundamental could no longer be distinguished, but the high tone persisted, and was clearly audible up to a distance of 13cm. The effect was very striking, and when the bullet was moved to and fro parallel to the plane of the coils E F at a distance of about 10cm., the telephone emitted a shrill whistling sound each time the sensitive area (H) was passed.

It was noticed that other metals, such as iron, brass, and copper, did not seem to reinforce this high tone to any great extent, but brought out the fundamental at every distance where an effect was produced.

Exp. 7. The condenser G (Fig. 17) was removed from the circuit and the leaden bullet held about 4 or 5 cm. from the coils E F. The fundamental tone was heard, and the characteristic upper-partial could also be distinguished, but it was only faintly audible. Upon now suddenly replacing the condenser the high upper-partial tone was instantly reinforced as if by a resonator.

Exp. 8. The rheotome employed to interrupt the primary circuit (which had been placed in a distant room) was found to be vibrating badly. The reed I of the instrument (see also Fig. 5) was rattling against its contact pieces, thus producing an impure sound, and I could distinguish amongst the upper-partials the tone that had been reinforced by the condenser. Upon screwing up the contact pieces so as to improve the vibration I could no longer distinguish the particular upper-partial referred to, and upon returning to the room in which the coils E F (Fig. 17) were placed I could no longer detect the effects noted above in Exps. 6 and 7, and the hearing distance did not exceed 9 cm.

The peculiar effects obtained with the arrangement shown in Fig. 17 thus seemed to depend (1) *upon a particular kind of vibration of the reed of the interrupter, producing a certain high upper-partial or overtone,* (2) *upon the use of a condenser acting as a sort of electrical resonator for this tone, and* (3) *upon the use of the metal lead.*

(TO BE CONTINUED.)

THE FAURE ELECTRIC ACCUMULATOR COMPANY (Limited), 71, Queen Street, Queen Victoria Street, London, E.C.---NOTICE is hereby given that the SUBSCRIPTION LIST for 25,000 Preference Shares in the French Electrical Power Storage Company, Limited, will CLOSE on SATURDAY, the 30th day of December, 1882, for LONDON and the COUNTRY.---Subscriptions received at the London and County Banking Company, Limited, 21, Lombard Street, London, E.C., and Branches.

By order, HERBERT CANNING, Secretary.

THE FAURE ELECTRIC ACCUMULATOR CO., LIMITED,

OFFERS FOR PUBLIC SUBSCRIPTION

25,000 Preference Shares of the French Electrical Power Storage Company, Limited

These Preference Shares, numbered 1 to 25,000, inclusive, are redeemable in 30 years, from the 1st of January, 1884, at £20 or 500 francs, per share, by drawings as set forth in the tabular form hereunto annexed.

Pending their redemption, these shares will be entitled to a half-yearly payment of interest of six shillings, or seven francs fifty centimes, per share, on and after the 15th of July, 1883, such interest to be payable at the offices of the Faure Electric Accumulator Company (Limited), in London and Paris.

The payment of the interest on the said 25,000 shares is absolutely guaranteed by the Faure Electric Accumulator Company (Limited).

These shares will further participate, in their due proportion, in the 25 per cent. of the profits of the French Electrical Power Storage Company (Limited) reserved to the preference shares of that company, as set forth in its Articles of Association.

These shares are offered for public subscription at the price of £12 sterling per share, payable as follows:—£1 per share on Application; £2 per share on Allotment; £3 per share on February 15th, 1883: £3 per share on April 15th, 1883; £3 per share on July 15th, 1883.

Any subscriber paying up his shares in full on or before the 15th January, 1883, will be entitled to a discount of six shillings per share, and will further be entitled to a share certificate to bearer, free of charge.

No. of Shares to be drawn in—

1884	525	1892	666	1900	844	1908	1,069
1885	541	1893	686	1901	869	1909	1,102
1886	557	1894	706	1902	895	1910	1,135
1887	574	1895	728	1903	922	1911	1,169
1888	591	1896	750	1904	950	1912	1,204
1889	609	1897	772	1905	978	1913	1,228
1890	623	1898	795	1906	1,008		
1891	647	1899	819	1907	1,038		25,000

The utility and the practical and economic value of accumulators is to-day universally acknowledged, and it is sufficient on this head to cite the speeches and written testimony of Sir William Thomson, Professors Ayrton and Perry, Sylvanus Thompson, and Messrs. Cromwell Varley, Clarke Forde, and Co., Niaudet, Hospitalier, Franck Géraldy, and numerous other eminent electricians.

It is only by means of accumulators that can be solved the problem of the production on a large scale of electric energy, either at the pit's mouth or by the utilisation of waterfalls and other natural forces, and its transport by means of cables, for the purpose of distribution and consumption in industrial centres hundreds of miles distant.

The accumulators patented by Messrs. Faure, Sellon, and Volckmar are certainly the only ones in existence that are practical and economical; indeed, in consequence of the great progress that has been made in their manufacture, it may be calculated that the cost price of a ton of accumulators does not exceed £30 sterling, nor their maintenance more than £6 sterling, for a useful yield of 2,000 ampere-hours, during six hours, which is equal to effective work of more than 30 horse-power hours.

The French Electrical Power Storage Company (Limited) possesses the exclusive right to make, sell, and exploiter the Faure, Sellon, and Volckmar Accumulators in France and the French colonies, and the profits to be derived from the monopoly of a like invention for a country like France are incalculable. Some idea of these profits may be arrived at from the fact that the lighting alone of the City of Paris costs annually more than £3,000,000 sterling, and the motive power in the same city exceeds 25,000 horse-power.

The French Electrical Power Storage Company (Limited) has already ceded its rights for the Departments of the Seine, Seine and Oise, and Seine and Marne, to the French Metropolitan General Electric Company (Limited), which has been formed with a capital of £1,200,000, but the French Electrical Power Storage Company (Limited) retains 50 per cent. of the profits of the new company, in addition to the exclusive right of supplying accumulators and other apparatus at remunerative prices.

Negotiations are in progress for the formation of similar companies in other departments of France on like conditions.

The first series of 25,000 Preference Shares in the French Electrical Power Storage Company (Limited) is now offered to the public by the Faure Electric Accumulator Company (Limited), at the price of £12 per share, and at this price these Preference Shares will yield a fixed revenue of 5 per cent., payable half yearly; and, as they are further redeemable by drawings in 30 years at the price of £20 sterling—or 500f.—the bonus of this drawing, which amounts to £8 per share, is equal to a further annual dividend of more than 3 per cent., without taking into consideration their proportional part of the 25 per cent. of the surplus profits to which these Preference Shares are entitled.

The Faure Electric Accumulator Company (Limited) guarantees the fixed payment of interest on these shares, and, consequently, the holders thereof will, as to the interest, be virtually debenture holders of the said Faure Company, as well as shareholders in the French Electrical Power Storage Company (Limited).

Subscribers to this issue will be entitled to subscribe on similar terms to all other issues which may be offered to the public.

Subscriptions will be received in London by

THE LONDON AND COUNTY BANK, Limited, 21, Lombard Street, E.C.

FORM of APPLICATION for PREFERENCE SHARES of the FRENCH ELECTRICAL POWER STORAGE CO. (Lim.).

To the Directors of the Faure Electric Accumulator Co. (Lim.), 71, Queen-street, Queen Victoria-street, London, E.C.

GENTLEMEN: Having paid to the London and County Bank (Limited) the sum of pounds, being a deposit of £1 per share on Preference Shares in the French Electrical Power Storage Company (Limited), I hereby request that you will allot me that number, upon the terms of the annexed Prospectus, and I agree to accept the same, or any less number you may allot to me, and to pay the deposit upon allotment of £2 per share.

SLIP

MARANHAM AND PARA.—The cable between Fortaleza and Maranham is now repaired.

EASTERN ELECTRIC LIGHT AND POWER COMPANY.—Mr. Walter Jackson has been appointed secretary of this company.

ELECTRIC LIGHTING IN BRISBANE.—A company is being formed in Brisbane, Queensland colony, to introduce and work the Brush system.

BRAZILIAN SUBMARINE TELEGRAPH COMPANY.—The traffic receipts of this company for the week ended December 29, 1882, amounted to £3,095.

THE MAGAZINES.—The *Zoophilist* for January contains an article by Mr. St. George Lane-Fox on the humane slaughter of aged horses by electricity.

MR. FAWCETT.—The Postmaster-General is, we are glad to be able to announce, so far convalescent that all apprehensions as to his complete restoration are now entirely removed.

THE GREAT NORTHERN TELEGRAPH COMPANY.—This company give notice that 50 debentures, issued by the company, and variously numbered, have been drawn for payment.

THE TELEGRAPH IN BRITISH GUIANA.—Since the introduction of the sixpenny rate, says the *Colonies and India*, the number of telegraphic messages sent within this colony has increased nearly fourfold.

NEW TELEGRAPH OFFICE AT MELBOURNE.—It is stated that the Victorian Government have decided to erect a new central telegraph office in Melbourne, next to the General Post Office. It is to cost about £17,000.

POSTS AND TELEGRAPHS IN VICTORIA.—The revenue derived by the colony of Victoria during 1882 from the postal and telegraphic services amounted to £312,000, or an increase of £27,000 over the revenue from the same sources in 1881.

BUSINESS NOTICE.—The business of E. Fox and Co., of Millwall, wire manufacturers, has been turned into a limited liability company, under the title of Edwin Fox and Co. (Limited), and the City offices are at 5, Great Winchester-street, E.C.

THE FERRANTI DYNAMO MACHINE.—We are informed that the Australasian Electric Light and Power Company have taken the sole agency for the Ferranti dynamo-electric machine in the Australias, and the first machine will be sent out shortly.

WESTERN AND BRAZILIAN TELEGRAPH COMPANY.—The traffic receipts of this company for the week ending December 29th, 1882, were £2,036, after deducting the "fifth" of the gross receipts payable to the London Platino-Brazilian Telegraph Company.

THE MARSEILLES-BARCELONA CABLE REPAIRED.—The Direct Spanish Telegraph Company inform us that their cable between Marseilles and Barcelona is restored, and that telegrams for Barcelona and other places in Spain can again be sent by that route.

DIRECT COMMUNICATION BETWEEN LONDON AND SPAIN.—The Direct Spanish Telegraph Company having acquired a special wire between London and Falmouth, the direct Spanish cable to Bilbao is now worked direct from the company's station, No. 1, Leadenhall-street, E.C.

ELECTRIC LIGHTING COMPANIES' CAPITAL.—The *Journal of Gas Lighting* says that at the end of last year (1882) "the nominal capital of the various registered electric lighting companies amounted to £24,895,500; of which, however, not quite three millions sterling appear to have been actually paid up by the public."

MR. SWAN.—Mr. J. W. Swan, the inventor of the incandescent lamp so well known by his name, is about to take up his abode permanently near London, instead of Newcastle-on-Tyne, this migration being occasioned by the pressing claims which the Swan United Electric Light Company's business has upon Mr. Swan's time.

HONOURS FOR AN ELECTRICIAN.—Herr Bunsen, the celebrated inventor of the Bunsen battery, has been elected a Foreign Associate of the Academy of Sciences, Paris. There are but eight such associates, of whom Sir William Thomson is the only one besides Herr Bunsen whose name can be said to be connected with electrical science.

CUBA SUBMARINE TELEGRAPH COMPANY.—The number of messages passing over the lines of this company during the month of December was 2,954, estimated to produce £2,800, against 2,672 messages, producing £2,741, in the corresponding month of last year. The traffic receipts for the month of September, estimated at £2,250, realised £2,283.

ELECTRIC LIGHTING FOR TRAINS.—A telegram, dated Vienna, December 31, which appeared in a daily contemporary, says:—"Experiments have recently been making for the application of the electric light to the trains of the Southern Railway of Austria, and in a few days the first electrically lighted train will be run from Vienna to Neustadt."

THE TELEPHONE IN PORTUGAL.—The Edison Gower-Bell Telephone Company of Europe have recently obtained a royal subscriber to their Lisbon exchange in the person of the King of Portugal. His Majesty, in addition to the line leading to his palace, is having his private apartments connected with the various ministries and the opera by the same company.

WEST INDIES AND BRITISH GUIANA.—The cable between Antiqua and Guadeloupe is repaired, and telegraphic communication restored with Guadeloupe, Dominica, Martinique, St. Lucia, St. Vincent, and Barbadoes. The cables between St. Croix and Trinidad, and between Trinidad and Demerara, however, are now interrupted, and as the cable between St. Vincent and Greneda is not yet repaired there is no telegraphic communication with Greneda, Trinidad, and British Guiana.

PERSONAL.—From an American contemporary, one of whose columns is marked with the blue pencil considered requisite to catch editorial eyes, we learn that Dr. H. R. Rogers, of Dunkirk, New York State, has been elected a corresponding member of the New York Academy of Sciences. Dr. Rogers is not unknown to our readers. We recently printed a lengthy article from his pen, entitled "The Primordial Force." We are glad to chronicle the honour conferred on Dr. Rogers.

THE EDISON SYSTEM IN THE "CITY TEMPLE."—During service on the last day of the old year, the whole of the Edison lamps by which the City Temple is lighted were extinguished, owing, we believe, to some breakdown in the machine room. Dr. Parker assured his congregation there was no danger, and fortunately no panic occurred. Nothing can provide against a breakdown of machinery but accumulators, and accidents of this kind emphasise their necessity. Dr. Parker is to be congratulated on his coolness and tact.

THE PARIS EXHIBITION.—In the last issue of *La Nature* is a very good illustration of the medal struck in commemoration of the Great Electrical Exhibition of 1881, held in Paris. On the face of the medal is an allegorical figure representing Science, in the form of a goddess, lighting by means of lightning the torch with which she illumines the world. On the reverse side are engraven the names of M. Grévy, President of the French Republic; M. Cochery, Minister of Posts and Telegraphs; and M. Berger, the Commissary-General of the Exhibition.

PROFESSOR PALMIERI.—In its obituary for 1882, our excellent contemporary, the *Daily News*, perpetuates an error which was, we believe, first made public by a French paper. We ourselves must plead guilty to having been taken in by it at the outset, but on ascertaining our mistake, did our best to correct it. The error alluded to is the announcement of the death of Professor Palmieri, of Italy. The fact is that a male relation of the Professor has passed away during the year, but not the professor himself, who, we have have every reason to believe, is hard at work in his observatory on Mount Vesuvius, and in good health.

THE TELEPHONE IN AUSTRIA-HUNGARY.—On the 25th October, 1882, there were in Buda-Pesth 320 subscribers to the Local Telephone Exchange out of a population of 320,000. At Trieste, on the same date, there were 50 subscribers to the exchange there out of a population of 112,000. The exchanges at both these places belong to the Central Telephon Gesellschaft, of Vienna. This company has obtained Government concessions for the establishment of exchanges in Graz, Lemberg, Krakan, Brünn, and Temesvar, but these are not yet working. The price of the annual subscription is 180 florins in Pesth and 90 florins in Trieste. The length of the company's concession in Pesth is 20 years, and in Trieste 10 years.

ELECTRICAL ENGINEERING.—Professor W. Grylls Adams, F.R.S., will deliver a course of lectures on Voltaic and Dynamic Electricity and Magnetism, and their applications to Cable-testing, Electric Lighting, &c., at King's College, Strand, W.C., during the ensuing session. A course of practical work in electrical testing and measurement with especial reference to electrical engineering will also be carried on under his direction in the Wheatstone laboratory. The lectures will be given once a week, on Mondays, at 2 p.m., and the laboratory will be open daily (Saturdays excepted) from 1 to 4. The work will begin on Monday, January 15. For further particulars apply to Professor Adams, King's College, London.

THE EASTERN TELEGRAPH COMPANY.—This company have just issued a revised edition of their tariff book, which contains all the latest changes in tariffs, &c., up to December last. It is a model of what a book of its class should be, and that is the highest praise we can bestow upon its compilers. In addition to the usual information as to tariffs, the book contains no less than ten maps, splendidly engraved on steel, on which the various cables and chief landlines of the world are marked in colours. The Eastern Telegraph Company are to be congratulated on the enterprise which produces such a book as that now lying before us. We may mention that the maps have been engraved, and the book printed by Messrs. Waterlow and Sons, of London-wall, E.C.

ELECTRIC LIGHTING AT WILLIS'S ROOMS.—One of the most successful incandescent installations yet made is that in Willis's Rooms, which were lighted up for the first time on Tuesday night by the Metropolitan (Brush) Electric Light and Power Company. The work, owing to the confined space at disposal, and to other local circumstances, was one of exceptional difficulty. The lighting, however, elicited warm expressions of approval from the numerous company assembled. The work has been carried out to the satisfaction of Mr. Musgrave Heaphy, C.E., of the Phœnix Fire Insurance Company, who superintended the installation on Messrs. Willis's behalf. The existing chandeliers and brackets were utilised without any disfigurement of wall or ceiling.

ROUNDABOUT TELEGRAPHY.—At a recent meeting of the Falkirk town council Councillor Allan directed attention to the delays in telegraphing from Falkirk to Glasgow, and also to Grangemouth, on account of Falkirk not having any direct communication with these places. At present a message can be sent quicker by rail to Grangemouth than by telegraph, because a telegram is first sent to Edinburgh, then retransmitted to Glasgow, and ultimately sent direct from Glasgow to Grangemouth. In the same way all telegraphic messages to and from Glasgow have to be sent first to Edinburgh and retransmitted. It was unanimously resolved to memorialise the Postmaster-General, requesting that Falkirk should be placed in direct telegraphic communication with both Grangemouth and Glasgow.

THE ELECTRIC LIGHT AND TEXTILE MANUFACTURERS.—The Mayor and Corporation of Leicester and the leading manufacturers visited the hosiery manufactory of Messrs. Corah, Sons, and Cooper, Leicester, last week, to witness the first introduction of the electric light into a textile factory in the town. The many shades of yarns used in ladies' jerseys and other fancy fabrics make it difficult to manufacture and make up these goods by gas light, but on this occasion it was proved that colours undistinguishable by gas light were easily matched by the electric light. The Brush arc and Swan incandescent lamps are used. Leicester is not the first town by any means where this fact has been ascertained, and many textile manufacturers and dyers have adopted the electric light, including the well-known Messrs. Fuller, of Perth.

A COMBINATION.—The Gramme Electrical Company, of New York, controls the American patents belonging to the following companies:—The American Electric Company, of New Britain, Connecticut; the Brush Electric Company, of Cleveland, Ohio; the Edison Electric Light Company, of New York; the Fuller Electrical Company, of New York; the Jablochkoff Electric Lighting Company, of New York; the United States Electric Lighting Company, of New York, and the Weston Electric Light Company, of Newark, New Jersey; and has given notice that it will prosecute any one infringing any such patents. It appears from a list lying before us that the earliest of these patents was taken out by Farmer on December 12, 1865, and relates to a thermo-electric battery. The total number of patents controlled by the Gramme Company, according to this list, was, on the 1st November last, 389, and included everything relating to electric lighting and the distribution of electricity, as well as some miscellaneous patents.

PROPOSED EXTENSION OF THE TELEGRAPH IN SHETLAND.—A long correspondence has taken place between Mr. Garriock, of Reawick, Shetland, Mr. Laing, M.P., and the Postmaster-General, with reference to the proposal to extend the telegraph system to the principal fishing stations on the west side of Shetland, the curers and fishermen there being under great disadvantage, particularly in the herring-fishing season, when some hundreds of boats from ports on the east and west coasts of Scotland are engaged in that industry. The Post Office and Treasury decline, says the *Scotsman*, to extend the line from Lerwick to Walls and Reawick unless a guarantee

Digitized by Google

be given by the inhabitants of £255, for seven years, a total guarantee of over £1,700; while Mr. Garriock maintained that the above line can be constructed for less than £1,000. It having been proposed to get a guarantee out of the herring brand fund instead of a money grant, Mr. Laing has communicated with Lord Rosebery, who writes that he has forwarded the communication to the new Fishery Board.

An Electric Train-starting Clock.—A very ingenious electric clock for use in railway stations has been recently exhibited in Boston. It gives automatically the signals for starting trains at the proper times, and it is automatically regulated at noon each day by electric impulse from some astronomical station. Though the details of the apparatus are rather complicated, the principle is simple. The mechanism for giving the signals shows two discs, each pierced with 1,440 holes, arranged in spirals of 24 turns, with 60 holes in each turn. Small metallic pegs are inserted in the holes corresponding to any given minute and hour, and the contact of these with an electric conductor allows passage of the current for the signal. When any change is made in the time of starting trains the pegs are shifted. One, two, three, or more successive and different signals can be given for each train. It is proposed, says *The Times*, to connect all the stations of a railway with the main office, so that signals for starting trains will be given from a single apparatus.

Human Hair for Carbon Filaments.—Mr. William Stanley, jun., of Bergen, New Jersey, U.S.A., has recently patented, through his agent, Mr. J. Wetter, a mode of preparing human and other hair, preferably human, for making carbon filaments for incandescent lamps. In his patent he remarks:—"It has been found that the hair of the human head is superior to that of the lower animals for making carbons for the purpose indicated, and that the hair of Chinamen gives the most satisfactory results. This is probably due to the circumstance that the hair of the Chinese, so far as it has been examined, is coarser than that of most races, and is remarkably straight and uniform in cross section." But how about the sacredness of the Chinaman's pigtail? Perhaps Mark Twain's heathen Chinee might be got to part with his tail for a consideration, but we doubt if any Chinaman with the least atom of self-respect would do so, not even to become the means of thereby enlightening the world after a celestial manner. The number of Mr. Stanley's patent is 2,660, June 7, 1882.

A Dictionary of Electricity.—This is the title of a work by Mr. Henry Greer, which is published by the College of Electrical Engineering, 122, East Twenty Sixth-street, New York, at the price of two dollars. As we have not seen a copy of the work in question we cannot speak as to its merits, but it appears to have been thought well of by Edison, Brush, and other authorities. For the benefit of our American friends who are good enough to send us slips of paper containing announcements of new works, &c., with appetising promises of future advertisements if we notice the same, we may remark that we are not, and never have been, in the habit of giving an opinion upon anything we have not seen and tested for ourselves, or of which we have not trustworthy information. If they will send us the books, instead of the slips of paper, they will put us in a better position to give an opinion. As regards the promises of advertisements, there may be English papers who will put the notices in with the hope that the promises as to future advertisements will be fulfilled—who will, in fact, sell their literary soul for a little money. We do not believe there are many such. However that may be, we must beg our transAtlantic correspondents of the class above-mentioned to keep such blandishments for those who appreciate them, and not to cast their pearls before such swine as ourselves.

Electric Lighting by Accumulators.—The offices of Messrs. Foster and Braithwaite, 27, Austinfriars, E.C., are now lighted by means of Lane-Fox incandescent lamps, fitted on the gas standards originally in use. The number of lamps employed at present is 24, of 20 candle-power each; it is intended, however, to increase this number to 30. The current is supplied by 25 Faure-Sellon-Volckmar accumulators, constructed by the Electrical Power Storage Company, of Great Winchester-street-buildings, E.C. These are fitted up in the cellar beneath the offices, and are charged by means of a small No. 2 Brush dynamo machine, driven by a 1 h.-p. Otto gas engine erected in the same cellar. According to the representative of the Electrical Power Storage Company, the E.M.F. of each of these cells is 2·15 volts, whilst they give a current equal to 800 ampere-hours when fully charged. The installation is a complete one of its kind, and includes all necessary switches, each light being readily turned off or on independently of the others, and one of Ayrton and Perry's ammeters. The lamps gave a very steady and good light when we saw them on Wednesday evening, and altogether the installation seems to have been carefully carried out. There appears to be a concensus of opinion amongst Messrs. Foster and Braithwaite's *employés* in favour of the new light over that of gas, mainly on account of the increased purity of the atmosphere in which they have to work.

Overhead Wires and Public Safety.—Unless something unforeseen occurs, the arrangements of our towns and cities, the structure of our houses, the very habits of our daily life, says the *Builder*, are likely to be transformed by this subtle energy. To this end the companies are silently but rapidly working. And each day that they are so allowed to work not only stretches tons of additional wires over our heads, but goes to create at least the presumption of a vested right in the use of our housetops by the telephone companies. Let us suppose matters to go on just as they are now doing till the time when the earliest wires attain their natural period of durability, and that then, within a few weeks, we have a dozen cases of slaughter in the streets by the natural agency of the decaying wire. What will be the public excitement? What the demand for the immediate removal of the source of danger? What the cost of the hurried change? What the inconvenience? What the demands for compensation, to be provided by a legislature, and paid by a public, that took no heed of the growth of the mischievous and threatening mode of putting house in communication with house, until it was too late? The confusion will be something altogether without precedent. It is thus not only in the behalf of the one client for whom the scientific journalist holds a general retainer (viz., the public), but also on behalf of the telephone companies themselves, that we desire to join in the remonstrances now made, and to plead for the public safety.

Electric Lighting from a Business Point of View.—We take the following from Matheson and Grant's "Engineering Trades Report" for the last half year:—"Electric lighting is only slowly taking a place as a substitute for gas, the recent legislation in regard to the lighting of towns having tended in many cases to embarrass rather than simplify the inauguration of a new system. Applications for parliamentary powers have, however, been made by so many corporations and joint-stock companies that the coming year will doubtless clear away many of the difficulties, financial

Digitized by Google

and legal rather than scientific, which at present seem to stop the way. Meanwhile, the real truth in regard to the numerous undertakings for which capital was so freely subscribed a year ago is becoming manifest; and, as we ventured to point out in our July Report, the unremunerative nature of those companies which commenced business burdened with large capital already paid away for doubtful patent-rights, and unavailable, therefore, for the genuine expenses of working, will discredit really sound enterprises when they arise. The sale of subsidiary rights and patents is much more profitable to promoters than the carrying out of actual works, and the credulity of investors is even at the present time being taken advantage of for inventions practically valueless with an audacity which deserves exposure. The manufacture of the apparatus and its installation afford employment to engineers, but to them also it is interesting to note that the light is coming into increased use, not only for the carrying on of public works such as harbours, mines, and building operations at night, but as superseding gas in machine shops and factories."

The Telegraph and Steam Engine.—Mr. Courtney, M.P., in presiding at the annual meeting of the Royal Cornwall Geological Society at Penzance this week, referred to the introduction of the electric telegraph and the invention of the steam engine, by which electricity and steam had been made our slaves in almost all the operations of life. No doubt, Mr. Courtney is reported to have said, these were most remarkable applications, and we, in the present day, were greatly indebted to them; but, at the same time, he was bound to say that, in his opinion, we might overrate the debt. The conveyance of news by the telegraph was insignificant, if the news itself were not of importance. As to the diminution of toil which steam effected in supplying our wants, it depended very much on the use we made of it, and how far that did or did not confer a benefit on mankind. Was it a fact that, owing to the introduction of steam, the labour which was necessary for the subsistence of the multitude had been in any sense diminished, and the ragged edge of pauperism which surrounded the borders of society had in any sense disappeared? We might derive either of two advantages from the introduction of steam—we might either make life less toilsome while maintaining the mass of it as it was, or keep up the toil of life while increasing the mass, and he was afraid the result of the discovery of steam power had been an increase in the number of human beings rather than an improvement in the quality of life. He was, indeed, more disposed to reverence science for its educational than for what he might call its economic advantages, for the way in which it elevated the mind of man rather than for its ability to enable more men to live on the same low level on which men lived before.

On the Electrification of Air.—The following note has been presented to the Academy of Sciences, Paris, by M. Mascart:—At one of the meetings of the International Congress on Electrical Units, recently held in Paris, Sir W. Thomson called attention to the scientific interest which would attach to continuous observations on the electrification of the lower layers of the atmosphere, by determining the potential in a limited volume of gas taken from the surrounding air and removed from the action of foreign electrical masses. I endeavoured to ascertain, by experiment, how a quantity of air thus isolated preserves its electrification, in order to define the conditions necessary for continuous observation. The air of the amphitheatre of the Collége de France, which represents in round numbers a cube of 9 to 10 metres per side, was electrified by the discharge of a Leyden jar during 10 seconds through a conducting flame. An electrometer, placed in the room, was connected with a receiving flame placed at about 8 metres (about 26ft.) from the place of discharge, and 1·50 metres from the floor. As soon as the discharge began the electrometer was affected. The deflection was at first accompanied by a series of oscillations of great amplitude, then it increased in more regular manner, attained a maximum after 10 to 15 minutes, and afterwards slowly decreased. The primary large oscillations appeared to be due to a direct action of layers of electrified air on the conducting wires of the electrometer which were too near them. To eliminate this cause of error, the electrometer was placed in a neighbouring room, connection with the receiving flame being established by a wire which traversed the partition. In this case the effects were more regular; the maximum deflection was again attained in about a quarter of an hour, then it decreased slowly, following a law which the form of the curb clearly shows to be an exponential, as for caloric radiation. At the end of two hours, the potential was still 1-20th of its maximum value. A series of oscillations of small amplitude were again perpetually appearing, above all during the first part of the time, and these oscillations were enlarged on opening a door, even for a very short time, or when an observer crossed the room at several metres distance from the receiving flame. These phenomena are easily explained if we admit that the electrification remains adherent to the layers of air which have been directly in contact with the flame during the discharge. The electrified gases rise by reason of their high temperature, then are set in motion and disseminated after the manner of fumes, until they are uniformly distributed in the atmosphere of the room; the deflection of the electrometer is then nearly at its maximum. As to the disappearance of the electricity, it is occasioned either by exchange with the outer air, or by the receiving flame itself, which continuously neutralises the surrounding electricity, or by contact of the air with the sides of the room. The loss should be diminished when the movements of gas due to the presence of the flames are suppressed. This is shown by the experiment of discharging the jar by a sharp point, and replacing the receiving flame by a flow of water. The needle of the electrometer is still deflected directly after the commencement of the discharge, but it then remains stationary for some time, reaches its maximum deflection a little later, and returns to zero more slowly. At the end of an hour the loss was not more than two-thirds; it would, doubtless, have been much slower in an absolutely calm atmosphere. An indirect proof of this is furnished by watching the air enclosed in a room, having no means of communication with the outside but by the usual draughts through the doors and windows. We almost always find here electricity of the same sign as that of the outer air, for the opening of a window is sufficient to greatly increase the indications of the instrument. The result of these experiments is, that to examine the lower layers of the atmosphere it is sufficient to determine the potential in a room a few metres in area, the walls of which should be formed by a metal wirework with large meshes in connection with earth, in order to eliminate the action of external electrical objects. The exchange of gas with the atmosphere, however feeble the wind might be, would suffice to compensate for the loss produced by the walls and by the collecting apparatus (flame or flow of water), and to give to the electrometer a constant potential proportional to the electrification of the surrounding air. This potential will be quite different (more often than not of contrary sign) to that obtained by the usual methods.

ELEMENTARY ELECTRICITY.

V.

On the Energy of an Electrified System.

If a half-hundredweight be carried to the top of a mountain 1,000ft. in height, the work done against gravity will be 56,000 foot-pounds, and the height of the mountain will not be sensibly affected by the presence of the half-hundredweight on its summit. Generally, if w lbs. be raised to a height of h ft., the work done against gravity will be $w\,h$ foot-pounds.

Similarly, if Q units of electricity be brought from the earth to a place where the potential is V, and if this potential be supposed unaffected by the presence of the Q units of electricity, a supposition which we may make if Q be sufficiently small, then the work done against electrical forces will be Q V ergs, and this, therefore, will represent the *potential energy* due to the charge in its new position.

If a quantity of bricks, say, w lbs., be piled up on a horizontal plane so as to form a solid cylindrical tower whose height is h ft., a certain quantity of work will be done against gravity in raising the bricks into their position; but this will *not* be equal to $w\,h$ foot-pounds, for it is only the last course of bricks which is raised through the full height of h feet (neglecting the thickness of the bricks). If we consider the first and last courses together, we see that the *average* height through which they are raised is $\frac{1}{2}h$ feet, and, similarly, if we take the second and last but one, the third and last but two, and so on. Hence the work done in raising all the bricks into their positions is the same as if they were all raised through a height of $\frac{1}{2}h$ ft.; that is, to the height of the centre of gravity of the pile. Hence, the work done in raising the bricks into their positions is $\frac{1}{2}w\,h$ foot-pounds.

If the height of the tower be doubled, its base remaining the same, the weight of bricks will also be doubled, so that the product $w\,h$ will be increased four-fold, and, generally, the work done in raising the bricks into their positions will be proportional to the *square of the height* of the tower, if the area of the base be given. It is this law of increase which partly accounts for the great expense of erecting lofty buildings.

The case is precisely similar when a conductor is charged. Thus, if the conductor be initially uncharged and at potential zero, and if Q units of electricity be communicated to it, whereby its potential is raised to V, in virtue of its own charge, and of that alone, the work done in charging the conductor, and the potential energy of the system when charged, will be $\frac{1}{2}$Q V ergs. For, if we divide the charge into a very great number of equal portions, or "elements," the first element on entering the conductor finds it at zero potential, and no sensible amount of work has to be done in order to bring this element from the earth to the conductor. A little work will have to be done on the next element, and a little more on the third, and so on, but it is only the last element which enters the conductor when it is at potential V; and, since the potential of the conductor depends only on its own charge, the potential will, as explained below, at each instant be proportional to the charge which the conductor then possesses, and, therefore (as in the case of the tower of bricks), the *average difference of potential* through which the several elements of the charge are raised will be $\frac{1}{2}$V. Hence, the work done in charging the conductor will be $\frac{1}{2}$Q V ergs.

The *capacity* of a conductor was defined as the number of units of electricity required to raise it to unit potential, and this is a quantity which depends only on the form and dimensions of the conductor, and on its geometrical relations to other conductors, provided that the dielectric remain unhanged. Hence the potential to which a conductor will be raised by its own charge will be proportional to that charge, so that, if C denote the capacity of the conductor, Q its charge, and V the potential to which it is raised thereby, then

$$V = \frac{Q}{C}.$$

Thus, if the charge of a conductor be doubled, its potential will be also doubled, and the energy will be increased fourfold. Generally, the energy of a conductor which depends on its own charge only will be proportional to the square of its charge. If E denote the *energy* of a charged conductor when *isolated*, that is, removed from the inductive action of all other bodies, we have the following relations:—

$$E = \frac{1}{2}Q\,V = \frac{1}{2}\frac{Q^2}{C} = \frac{1}{2}C\,V^2,$$

so that we can express the energy in terms of the *charge* and the *potential*, or of the *charge* and the *capacity*, or of the *capacity* and the *potential*.

There is one other case to be considered. A tower might be built on the top of a mountain, but so lofty that its height could not be neglected in comparison with that of the mountain. Suppose that the height of the mountain above the brickfields is k ft., the height of the tower from base to summit h ft., and the weight of bricks employed w lbs. (The tower is supposed to be built without foundations.) Then the work done in lifting the bricks to the top of the mountain will be $w\,k$ foot-pounds, as in the first case considered, and the work done in lifting the bricks from the mountain top into their positions in the tower will be $\frac{1}{2}w\,h$ foot-pounds, as in the second case, so that the whole amount of work done in raising the bricks into their proper positions will be $w\,k + \frac{1}{2}w\,h$ foot-pounds, that is, $w\left(k + \frac{1}{2}h\right)$ foot-pounds. This result might have been obtained with equal readiness from the consideration that the height of the *centre of gravity* of the tower above the brickfields is $k + \frac{1}{2}h$ feet, whence the work done against gravity in raising the bricks must be $w\left(k + \frac{1}{2}h\right)$ foot-pounds.

Now, suppose that a conductor, though uncharged, is maintained at a potential V_1 by charged bodies in its neighbourhood, and that a charge of Q units of electricity is communicated to the conductor. Let V_2 be the potential to which the conductor would be raised by this charge alone. Then its final potential will be equal to $V_1 + V_2$. The first element of electricity which enters the conductor will be raised to potential V_1, and the last element to potential $V_1 + V_2$, the *average* difference of potential through which the electricity is raised being $V_1 + \frac{1}{2}V_2$, so that the work done in charging the conductor will be $Q\left(V_1 + \frac{1}{2}V_2\right)$ ergs, or $Q\,V_1 + \frac{1}{2}Q\,V_2$ ergs. The case is precisely similar to the tower just referred to, V_1 corresponding to the original height of the mountain k, which is independent of the presence of the bricks, and V_2 corresponding to the height of the tower h, which depends only on the bricks.

If C denote the capacity of the conductor in the position it occupies, *i.e.*, the charge which would raise it to unit potential if the other conductors were present but not separately charged, then, as before, $V_2 = \frac{Q}{C}$, and the second term in the expression for the work may be expressed in terms of the charge and capacity, or the potential and the capacity.

Instead of considering a tower of bricks, we might have drawn an illustration from a cylindrical vessel, into which water is pumped from a lake, the height of the surface of the water in the vessel depending on the quantity present. If the bottom of the vessel be on a level with the surface of the water in the lake, and the vessel be filled to the height of

Digitized by Google

h feet, with w lbs. of water, the average height to which the water is raised will be $\frac{1}{2}h$ feet, and the work done in pumping, or the energy of the raised water, will be $\frac{1}{2}wh$ foot-pounds.

If we suppose the height of the cylindrical vessel to be unlimited, and the height to which it may be filled with water limited only by the power of the pump or the strength of the vessel itself, we have a strict analogy with an electric conductor, a Leyden jar for instance, in which the lake corresponds to the earth, the pump to the electric machine, and the strength of the vessel to the strength of the dielectric to resist disruptive discharge. It may be remarked here that the *capacity* of a conductor has no necessary relation to the amount of electricity which can be put into it if a sufficiently powerful electric machine be employed. This is limited by the strength of the dielectric, while the capacity depends simply on number of units of electricity required to charge the conductor to unit potential, and would be the same even if the dielectric were so weak as to break down before the unit of potential were attained. If we say that a vessel can contain just a pound of water at 4°C, this serves practically to determine the volume of the vessel, for an enormous pressure would be required to increase the quantity of water by one-tenth per cent.; but the statement that a vessel can contain a pound of air at 0°C gives no idea of the the size of the vessel, unless the pressure of the air be also stated. The amount of air at 0°C which would fill the vessel to standard pressure is perfectly definite, and might be called the *capacity* of the vessel for *air*. Electric capacity is analogous to this.

Now, suppose we define the capacity of the cylindrical vessel, which, as above stated, is unlimited in height, as the number of pounds of water required to fill it be a height of 1ft. The capacity will then depend on the sectional area only. If c denote the capacity as thus defined, and if w lbs. of water be pumped into the vessel, and the surface be thereby raised to a height of h ft., we have $w = c\,h$. Also the work done in raising the water against gravity will be $\frac{1}{2}wh$ foot-pounds, and this will, therefore, be the potential energy of the raised water. Let it be denoted by e. Then we have

$$e = \frac{1}{2}wh = \frac{1}{2}\frac{w^2}{c} = \frac{1}{2}ch^2.$$

Now, let a second vessel of the same capacity be taken, and let the two vessels be connected by a tube at the bottom of each, and suppose that the second vessel is empty. On opening the communication between the two, one-half of the water in the first vessel will run into the second, the height of the surface in each will finally be $\frac{1}{2}h$ ft., and the energy of the water in each vessel, e', will be represented by

$$e' = \frac{1}{2}\cdot\frac{w}{2}\cdot\frac{h}{2} = \frac{1}{2}c\left(\frac{h}{2}\right)^2 = \frac{1}{4}e.$$

Hence the energy of the whole amount of water in the two vessels will be equal to $\frac{1}{2}e$, or only one-half of that which it possessed when it was all contained in one vessel. The other half of the energy was dissipated as heat, &c., when the water flowed through the pipe and dashed itself against the sides of the empty vessel.

If a third vessel of the same capacity be connected with the other two there will again be a flow of water, a lowering of the surface, and a further dissipation of energy. The energy of the water in each vessel will be $\frac{1}{9}e$, and the whole energy $\frac{1}{3}e$. Similarly, if the water be divided between n equal vessels, the whole energy will be reduced to $\frac{1}{n}e$. We must notice, however, that *the quantity of water* remains the same. If n be made indefinitely great the final condition is the same as if the water were allowed to flow back into the lake, and the energy is reduced to zero, *but the water*, of course, *remains*.

The case is similar when we have a Leyden jar of capacity C, charged to potential V with Q units of electricity. Denoting the energy of the charge by E, we have

$$E = \frac{1}{2}QV = \frac{1}{2}\frac{Q^2}{C} = \frac{1}{2}CV^2.$$

Now, suppose the inner and outer coatings of the jar connected with those of an equal, but uncharged, jar. The charge will then divide itself equally between the two, the potential of each will be reduced to $\frac{1}{2}V$, and the energy of each to $\frac{1}{4}E$, so that the whole energy of the system will be $\frac{1}{2}E$, while the remaining $\frac{1}{2}E$ units of energy will be dissipated in the spark which occurs.

If a third equal jar be now connected with the other two, the charge will be equally divided between the three, and each jar will then possess one-ninth of the energy possessed by the first jar before discharge, so that the energy possessed by the three jars together will be only $\frac{1}{3}E$, the rest of the energy having been dissipated in the sparks.

If the number of jars be still further increased the energy will be correspondingly diminished, so that when the charge is divided among n equal jars, its energy will be reduced to $\frac{1}{n}E$.

But throughout all these changes, associated as they are with the dissipation of the energy of the charge, the quantity of electricity with which we have to do remains absolutely constant, viz., Q units. Thus, work is done by the system, and electrical energy is transformed into heat, &c., but the quantity of electricity remains unchanged. When heat is employed in doing work, we not only have a general lowering of temperature, but a part of the heat, equivalent to the work done, is actually consumed in the process, being transformed into some other form of energy, and ceasing altogether to exist as heat. This is the case, because heat *is itself energy*, and nothing else. Therefore, we do not say that heat *possesses* energy, but heat *is* energy. The case of electricity, however, is very different. The electricity falls in potential, but none of it is lost or transformed into anything else. The charge remains unchanged. The analogy is to be found in the case of water or other heavy matter which does work as it falls from a high level to a low level, though the quantity of matter remains absolutely unchanged. Thus, we may say that water *possesses* energy in virtue of its situation relative to the earth, but we cannot say that water *is* energy. Similarly, electricity *possesses* energy in virtue of its potential, and can do work as its potential falls, but electricity itself *is not* energy, for however much work it may do, the quantity of electricity remains unchanged.

As the energy due to a charge of electricity does not depend on the charge alone, but on its mode of distribution, it is natural to inquire where this energy resides. Suppose that two equal flat plates, A and B, are insulated, and charged, the one positively, and the other negatively, but with numerically equal charges. Let them be placed opposite each other, like the plates of an air condenser, and very near together, so that there is only a thin plate of air between them. The potential of A will be positive, but very small, because the negative charge on B produces a negative potential at A, which is numerically not much less than the positive potential due to the charge of A itself. Similarly, the potential of B will be numerically small, but negative. The charge of each will increase the energy of the system, since the positive charge is at positive potential and the negative charge at negative potential.

Although the attraction between the charged plates may

Digitized by Google

be very great, yet not much work can be done by the charges moving up to and neutralising one another, because there is such a small distance through which they can move. Hence we should expect the expression for the energy in terms of the charge and potential of each plate to be small; which is the case. Now let the plates be removed to a greater distance from one another. The energy will be increased by the work done in separating the plates in the same way as the energy of the earth and a raised weight is increased when the weight is raised to a greater height, even though the attraction between them diminishes. Thus, the greater the distance between the plates the greater will be the energy of the system and the work done by the electric forces if they are allowed to coalesce, and the greater will be the numerical value of the potential of each, because it will be less affected by the opposite charge on the other, so that the expression for the energy of each plate in terms of its charge and potential will increase, as, of course, it should. Throughout the process the dielectric between the plates is in a state of strain, and though this strain is diminished as the plates recede from one another, the quantity of the dielectric which is exposed to it is increased in a greater ratio, so that, on the whole, the *energy* due to the strain is *increased*. That such a state of strain exists appears from the fact that, if the charges be sufficiently increased, a spark will pass producing rupture in the dielectric. If the dielectric be a solid, like the glass of a Leyden jar, the passage of the spark produces a permanent rupture in it. Thus, the glass of a Leyden jar is sometimes pierced by overcharging the jar, and the jar thereby rendered worthless. Now, before a hole can be blown through a piece of glass the glass must be in a state of strain, and it is only when the stress to which the glass is exposed exceeds its ultimate strength that it will give way. Hence, we infer that when the dielectric does not give way, it is still in a condition of elastic strain, the amount of which depends on the strength of the charge. It is the energy due to this elastic strain which constitutes the energy of the electrified system.

Hence the dielectric plays a much more important part than the conductor, if we may speak of relative importance when each is essential. In fact the conductor simply serves to transmit the electricity to the surface of the dielectric, and it is the dielectric which is the theatre of all electrostatic action. The conductor is simply an electrode which has performed its office as soon as the question belongs to *electrostatics*, the conductor itself being entirely unaffected by any electrostatic action. We may regard a conductor in its normal state as filled with the electric fluid, which is *perfectly incompressible*. When the conductor is positively charged, more electricity is forced into it through its electrode, but, since it is already full of incompressible fluid, this can only happen by some of its electricity being squeezed out through the surface of the conductor, and thus made to press upon the dielectric, the conductor remaining altogether unaffected. But the dielectric, like the conductor, is full of the electric fluid itself, but, unlike the conductor, it cannot allow the fluid to pass through its substance, so that as the charge is squeezed out through the surface of the conductor into the dielectric, the fluid in the dielectric is pushed outwards to make room for it, and the whole dielectric is thereby thrown into a state of strain, which diminishes as the distance increases, but which must be continued till another conductor is reached, which can protect the dielectric beyond it, by allowing free displacement of electricity through its own substance. When such a conductor is reached, electric displacement takes place across its surface, electricity from the dielectric being, as it were, squeezed into the conductor through its surface, the surface thus becoming negatively charged, while an equivalent amount must leave the conductor and go into the earth or elsewhere, otherwise it will be squeezed out of the conductor at the opposite face into the dielectric, and the state of strain will then be propagated still further. Thus, if a charged body be surrounded by a conductor which is put to earth, no electric action will be communicated beyond this conductor; but if the conductor be simply a metal shell, insulated and uncharged, the stress will be continued on the other side. Hence, the use of wire cages connected with the earth, &c., for the protection of intruments from electrical actions.

It will also be seen that all electric displacements must take place in *closed circuits*. In the discharge of a Leyden jar the circuit is completed on the one hand by the discharger connecting the coatings, and on the other by the glass of the jar, across every layer of which there is a displacement of a quantity of electricity equal to that which appears in the spark.

Also, according to this view, a conductor is positively electrified when electricity is squeezed out of its surface into the surrounding dielectric, and is negatively electrified when electricity is squeezed from the dielectric into the surface of the conductor.

MAGNETIC FORCE AND CURRENT.—III.

BY OLIVER HEAVISIDE.

(CONTINUED FROM PAGE 152.)

Coming now to the electro-magnetic problem, we have two distinct things to do. First to prove the properties stated in Arts. I. and II., pp. 6 and 32, as applied to the system of vectors therein defined, quite apart from any physical application (this will be comparatively easy with the aid of (4) and (3) above, which are the characteristic equations of the potential function, (3) giving ρ in terms of the second derivatives of P, and (4) giving P in terms of ρ and distances), and next, to show that magnetic force and electric current belong to the system.

Let A be any vector of no convergence, to be imagined by the fluid analogy. Its components will be represented by A_1, A_2, A_3, and similarly for other vectors. Derive from A its curl B. The fundamental relation between A and B is that the line-integral of A round any closed curve = amount of B passing through it. The components of B are expressed in terms of those of A by means of the equations. (Theorem II., p. 56)

$$B_1 = \frac{dA_3}{dy} - \frac{dA_2}{dz}; \quad B_2 = \frac{dA_1}{dz} - \frac{dA_3}{dx}; \quad B_3 = \frac{dA_2}{dx} - \frac{dA_1}{dy}. \quad . \quad (5)$$

If we differentiate B_1, B_2, B_3 with respect to x, y, z and add, we find that B has no convergence, for the sum is zero. Similarly, derive from B its curl C, and from C its curl D, and so on. They are all vectors of no convergence, simply because the first one, A, has none. Now the equations for the components of C, similar to (5) are

$$C_1 = \frac{dB_3}{dy} - \frac{dB_2}{dz}; \text{ \&c.}$$

In this last, substitute the values of B_1, B_2, B_3 from (5), and it becomes

$$C_1 = \frac{d}{dy}\left(\frac{dA_2}{dx} - \frac{dA_1}{dy}\right) - \frac{d}{dz}\left(\frac{dA_1}{dz} - \frac{dA_3}{dx}\right).$$

Re-arranging the terms, and adding and subtracting $\frac{d}{dx} \cdot \frac{dA_1}{dx}$, this becomes

$$C_1 = -\left(\frac{d^2A_1}{dx^2} + \frac{d^2A_1}{dy^2} + \frac{d^2A_1}{dz^2}\right) + \frac{d}{dx}\left(\frac{dA_1}{dx} + \frac{dA_2}{dy} + \frac{dA_3}{dz}\right).$$

Here we at once recognise the quantity in the second ( ) to be the convergence (with sign changed) of A. But A has no convergence, so we are reduced to the quantity in the first ( ). Compare with Equation (3) above. For A_1 write P, and for C_1 write ρ. Since (4) is the solution of (3), or P the potential of ρ, therefore in the present case A_1 is the potential of C_1. Similarly we shall find A_2 to be the potential of C_2, and A_3 of C_3. Now compound A_1, A_2 and A_3, and we obtain the vector A. Similarly compound C_1, C_2 and C_3, and we get the vector C. Therefore, A is the *vector*-potential of C.

Similarly B is the vector-potential of D, and so on.

Thus, whilst the operation of curling carries us one step down the scale, that of finding the vector-potential carries us two steps up. Which we may express, curl (curl A) = C, or

Digitized by Google

$(\text{curl})^2 A = C$; also A = potential C, therefore curl curl potential C = C.

We may now show that the operations curl and potential are commutative, or curl potential C = potential curl C. For

B = potential D; just proved.
= potential curl C, by definition of D.
= curl A, by definition of B.
= curl potential C; just proved.

Therefore, B = potential curl C = curl potential C.

We may thus find any one of the series from the next following by either first going up two steps by the potential and then down one by curling, or else by first going down one step and then up two. *E.g.*, given C, to find B, we may go up to A and down to B, or down to D and up two steps to B.

This roundabout method may be replaced by a single operation—very complex, however, though for single elements easily enough understood; that is to say, we may find B direct from C without reference to the other vectors. The operation has no name; since its effect is the inverse of curling, we might denote it by $(\text{curl})^{-1}$, just as we might denote vector-potential by $(\text{curl})^{-2}$, thus indicating its property.

The vector-potential of an element of C, say c at a point Q distant r therefrom, is $a = \frac{c}{4\pi r}$ directed parallel to c. (Small letters when referring to elements.) Let the direction of c be parallel to z. Then

$$a_1 = 0; \qquad a_2 = 0; \qquad a_3 = \frac{c}{4\pi r}$$

express the components of a at Q. Find the curl of a by equations (5) above, thus,

$$b_1 = \frac{c}{4\pi}\frac{dr^{-1}}{dy} = -\frac{cy}{4\pi r^3}; \; b_2 = -\frac{c}{4\pi}\frac{dr^{-1}}{dx} = \frac{cx}{4\pi r^3}; \; b_3 = 0.$$

Now let h be the perpendicular from Q on to the axis of the current (the axis of z), and let the x-axis be parallel to h, so that $y = 0$ and $x = h$, the origin being at the element. Since $b_3 = 0$, b is in the plane of x, y, and since $y = 0$, therefore $b_1 = 0$, and

$$b = \frac{ch}{4\pi r^3} \text{ perpendicular to } r \text{ and to } h \quad . \quad (6),$$

with right-handed rotation about the axis of the current when we look along it the way the current is going.

The lines of b are, therefore, circles about the axis of c in planes perpendicular to it, and the strength of b varies inversely as the square of the distance from c, and is at the same time proportional to $\frac{h}{r}$, which is the sine of the angle between r and the axis of c. Every element of c must be understood to produce such a system b, and the vector-sum of the whole will give the complete value of B. Thus,

$$B = \text{v.}\Sigma\frac{ch}{4\pi r^3} = \text{v.}\Sigma - \frac{c}{4\pi}\frac{dr^{-1}}{dh} \quad . \quad . \quad . \quad (7)$$

In an exactly similar manner A may be expressed in terms of B, or C in terms of D. Thus, to express A in terms of B, change B into A and c into b in (7).

[The above method of expressing $(\text{curl})^{-1}$ C was obtained by finding the curl of the vector-potential of an element of C. We shall get exactly the same result by finding the vector-potential of the curl of an element of C. Thus, take a cylindrical element, of length ds, circular section πa^2, radius a. Current-density c, directed parallel to axis ds. The surface-curl of c is (see p. 8) of strength $\frac{c}{\pi a^2}$ directed in circles about the axis on the curved portion of cylinder.

Now, the vector-potential of a unit circle of radius a, when a is indefinitely small, may be obtained from equation (9), p. 104, by taking the first term only of the series, viz., $\frac{h}{r^3} \times 2\pi a^2 \times \frac{1}{2} = \pi a^2 \frac{h}{r^3}$.

Or, without making use of the equation (9) for a finite, let $\frac{a}{r}$ in the previous equation (6), p. 103, be indefinitely small, and expand $\frac{1}{\rho}$ by the binomial theorem, thus $\frac{1}{\rho} = \frac{1}{r} + \frac{ha\sin\phi}{r^3}$, therefore we get

$$\int_0^{2\pi} \frac{a\sin\phi}{\rho}\, d\phi = \int_0^{2\pi} \frac{ha^2}{r^3}\sin^2\phi\, d\phi = \pi a^2 \frac{h}{r^3}$$

as before. Multiply by $\frac{c}{\pi a^2}$ and we get the required vector-potential of curl of c, viz., $\frac{ch}{r^3}$, which, when divided by 4π to suit our present definition of potential, agrees with (6).]

At a distance r from a small plane closed curve great compared with its linear dimensions, its form is immaterial. The vector-potential is $\frac{h}{r^3} \times$ area, directed perpendicular to h and r.

We are now able to make another step. We proved before that when a vector has no curl anywhere, the vector itself is the space-variation of P, and P is the potential of the negative convergence of the vector. Now, our vectors A, B, C ... have curl, but not necessarily everywhere, and by Theorems II. and III., pp. 56-7, a vector may be derived from a scalar potential function wherever it has no curl. But A, B, C have no convergence anywhere, so the scalar potential cannot be found in the same manner for a vector which has curl in some parts of space and not in others, as for a vector which has no curl anywhere, (in which case (4) is the solution). To find the nature of the scalar potential for a vector of no convergence, let the vector c be confined to the boundary of a small plane area dS, *i.e.*, let c circulate round the closed curve bounding dS, and be nothing everywhere else. The vector b, of which c is the curl, must be derivable from a scalar potential in all space except in c itself. Now, we know the vector-potential of c, viz., $a = \frac{ch\, dS}{4\pi r^3}$ perpendicular to r and h, where r is the straight line from c to the place where a is measured, and h the perpendicular from the latter on to the axis of c, and that its three components are

$$a_1 = \frac{c}{4\pi}\frac{dr^{-1}}{dy}dS; \; a_2 = -\frac{c}{4\pi}\frac{dr^{-1}}{dx}dS_1; \; a_3 = 0.$$

From these derive b by means of equations (5). Thus

$$b_1 = \frac{c}{4\pi}\frac{d}{dx}\frac{dr^{-1}}{dz}dS; \; b_2 = \frac{c}{4\pi}\frac{d}{dy}\frac{dr^{-1}}{dz}dS;$$

$$b_3 = -\frac{c}{4\pi}\left(\frac{d^2r^{-1}}{dx^2} + \frac{d^2r^{-1}}{dy^2}\right)dS.$$

Here consider b_3. Since $\frac{c}{4\pi r}$ is the scalar potential of a quantity of "matter" c collected at the origin, we have, by equation (3)

$$\frac{c}{4\pi}\left(\frac{d^2r^{-1}}{dx^2} + \frac{d^2r^{-1}}{dy^2} + \frac{d^2r^{-1}}{dz^2}\right) = 0,$$

everywhere, except at the origin. Therefore, $b_3 = \frac{c}{4\pi}\frac{d}{dz}\frac{dr^{-1}}{dz}dS$. Thus, b_1, b_2, b_3 are the components of the space variation of $-\frac{c\,dS}{4\pi}\frac{dr^{-1}}{dz}$, or, $\frac{c\,dS}{4\pi r^2}\cos\epsilon$, if ϵ is the angle r makes with the axis of c. Call it Ω, then,

$$b_1 = -\frac{d\Omega}{dx}, \; b_2 = -\frac{d\Omega}{dy}, \; b_3 = -\frac{d\Omega}{dz}.$$

This scalar potential Ω is of a singular nature. It varies inversely as the square of the distance, and as the cosine of the angle ϵ. It is evidently not the potential of any collection of matter at the origin, either wholly + or wholly −,

Digitized by Google

but we can show that it is the potential of equal amounts of + and − matter indefinitely near each other.

Coat the small plane area dS with matter of surface density m, so that its quantity is $m\,d$S. Its potential at Q, distant r, is evidently $\frac{m\,d\text{S}}{4\pi r}$. Now shift this matter through a small space dz in the + direction along the axis of c. Its potential at the same point Q will now be

$$\frac{m\,d\text{S}}{4\pi}\left(\frac{1}{r} - \frac{dr^{-1}}{dz}\,dz\right).$$

It is therefore increased by the amount $-\frac{m}{4\pi}\,d\text{S}\,dz\,\frac{dr^{-1}}{dz}$ or $\frac{m\,d\text{S}\,dz}{4\pi r^2}\cos\epsilon$. Hence if we coat the surface dS with a quantity $m\,d$S on its + side and with $-m\,d$S on its − side, at the small distance dz apart, the potential of the combination will be $\frac{m\,d\text{S}\,dz}{4\pi r^2}\cos\epsilon$. This becomes identically the same as Ω if we make $m\,dz = c$.

Up to the present the vectors A, B, C have been treated quite apart from whether any of them represented physical quantities, (although they may all be possible cases of velocity distribution in an incompressible fluid). The properties are true whether electric current or magnetic force exist or not. But the last step made, the nature of the scalar potential whose space-variation gives b, brings us into contact with magnetism, and will enable us to fit current and magnetic force into the system. One experimental truth suffices. A small plane electric current and a small magnet produce exactly similar fields of magnetic force, not too near them, when we reckon the + direction of the axis of the magnet to be from its S to its N pole, and that of the current to be such that when we look along the axis in the + direction the current circulates right-handedly about it. If the magnet is very small and also the current area, the similarity exists everywhere except very close to them. We may go *through* a current, but not *into* a magnet. Let the magnet and the current area be indefinitely small, then we may say there is exact similarity at any finite distance.

Now, the magnetic force of a magnet has been proved to be capable of being caused by an imaginary substance, free magnetism, having the same self-repulsive power as the imaginary free electricity, with the same law of force, viz., that of the inverse square, so that the magnetic force at distance r from a charge m of magnetism is $m \div 4\pi r^2$, and if this acts upon a charge m', the repulsion is

$$\frac{mm'}{4\pi r^2}.$$

If, then, our vector c stands for electric current, the "matter" producing the potential Ω must be magnetism, and since the unit of magnetism is expressible in terms of the fundamental units of length, mass, and time, we may define the unit current so that

$$(m\,d\text{S})\,dz = c\,d\text{S},$$

or, strength of pole × length = current × area,

either of which may be called the magnetic moment (of the magnet, or of the current). (Having nothing to do here with the electrostatic system of units, we do not introduce the factor μ for induced magnetisation.)

After having thus made use of magnetism, we might dismiss it for good. In fact, we might replace every magnetised particle by its equivalent electric current, according to Ampère's theory of magnetisation. This theory generally strikes one on first acquaintance as very fanciful, the idea of electric currents flowing round molecules being so difficult to swallow. But it explains magnetism, one mystery takes the place of two; and since we neither know what an electric current nor what magnetism is, it is well to abolish one of them, and there can be no question as to which it should be.

Having now identified C with electric current and B with its corresponding magnetic force, it will be as well to point out the modifications needed to suit the adopted unit magnetic pole and the common definition of potential. They were temporarily discarded in the consideration of the properties of A, B, C, in order to have a uniformity of relations, for otherwise the 4π's would not come in regular order. We must now remember that the force of a magnetic pole is of strength $\frac{m}{r^2}$ at distance r, but that a current c spreading from a centre has strength $\frac{c}{4\pi r^2}$. On the other hand, potential follows the rule $\frac{m}{r}$ or $\frac{c}{r}$ in both cases.

We, therefore, have

$$\text{Vector-potential of C} = \text{A} = \Sigma\frac{c}{r} = \text{v.}\,\Sigma\frac{bh}{4\pi r^3}.$$

$$\text{Magnetic force} = \text{B} = \Sigma\frac{dl}{r} = \text{v.}\,\Sigma\frac{ch}{r^3} = \text{curl A}.$$

$$\text{Current} = \text{C} = \frac{1}{4\pi}\text{curl B}.$$

$$\text{D} = \text{curl C}.$$

From the uniformity of properties of A, B, C, as originally defined, any one of them may be current, the one preceding it being its magnetic force, of which examples were given in Arts. I. and II. The same is, of course, true in the last system, except that the 4π's require shifting occasionally.

There is one more remark to be made. We started with A, a vector of no convergence, and of course C has also none. But we identified C with current. This is admitted to have no convergence in conducting circuits, and in Maxwell's theory it has none anywhere. Much confusion would arise were convergence allowed. All vectors below C are therefore also non-converging, but we have not shown that those above it are. For proof it is sufficient to observe that the vector-potential of a small plane closed current (components given above) is now converging, and that any current system may be built up of such closed currents. This makes the matter square.

In No. IV we shall come to further properties of A, B, and C relating to the kinetic energy of closed currents, and of current-elements.

Erratum.—Page 104, *dele* 2 in denominator.

THE (ELECTRIC) CONDUCTIVE AND INDUCTIVE CIRCUITS GEOMETRICALLY ILLUSTRATED.

BY F. C. WEBB, M.I.C.E.

(CONTINUED FROM PAGE 128.)

When a battery (C A, Fig. 38) has one pole, C, to earth and the other pole, A, is suddenly placed in contact with a long conductor, A B, of considerable electrostatic capacity, (such as a long submarine cable), having its other end, B, insulated, an appreciable time passes between the moment of contact and the wire becoming fully charged to the same potential throughout as the full electromotive force of the battery. The first effect is much the same as if the battery were placed on short circuit. The potential at the pole A, which is attached to the wire, therefore sinks to some point near the datum line. Some of the electricity produced in any indefinitely small fraction of time is absorbed in satisfying the charge in the portions of the surface of the wire nearest the battery, and the rest passing on to the wire beyond. A portion of this, again, is divided in the same way, a part going towards charge and the balance on in current, and, in fact, it is an action in which both the conductive and inductive circuits are both in play at any section. The current at any moment is therefore greater at the part near the battery than further on, for any section receives more electricity than it passes on, otherwise the density of the electricity could not increase. The potential line at any moment is therefore a curve, with its concavity upwards, indicating a decreasing strength of current towards

Digitized by Google

the insulated end. As the charging of the wire becomes satisfied a greater proportion of the electricity received at any section is passed on. Thus the curve of the potential line continually becomes flatter until the wire is finally charged up to the full potential, and the potential of the battery pole A has risen again to a potential equal to the full electromotive force of the battery. Thus in the figure, after a very small instant, the curve of potential in the wire would be something like the curve No. 1, the potential at A having fallen from A F to A 1. In the next instant it would be 2, 2, 2; then 3, 3, 3, 4, 4, 4, and 5, 5, 5; and lastly, the wire would be charged to the full potential F G.

If the end A is now placed to earth, the electricity would pour out at A; but as at any part the electricity must be flowing through from any section faster than any electricity is supplied from the parts beyond—for otherwise that section could not become discharged—the current is at any moment stronger near the end to earth than at any part further

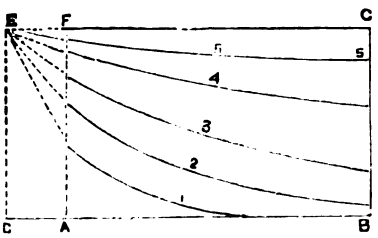

FIG. 38.

remote. The line of potential at any moment must therefore be steeper near the end to earth A than at any part beyond, and the curve of the potential line must, therefore, have its concavity downwards. Moreover, as the end B, the point furthest from the end to earth, has always to give up electricity to the parts nearer to the battery, the highest point of the curve must always be at the end B. Finally, as the wire becomes discharged, the proportion of electricity passing away from any section will constantly approach more nearly to the quantity it receives from the portions beyond it, for the resistance from any section to the end to earth is constantly the same, whilst the potential at every point is decreasing, so that all the currents are becoming less and less and more equal. Thus the potential line at different moments would become flatter, and would take the form somewhat of the curves 1, 2, 3, 4, and 5 in Fig. 39, the last curve indicating a very small current, but much more equal throughout than the state of the currents at the beginning of the discharge. The time of these changes

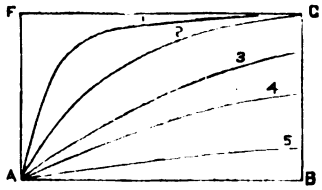

FIG. 39.

in the line of potentials are, no doubt, very different. That is to say, the curve 1 would, perhaps, occur in a minute fraction of a second after contact, but the time occupied between curve 5 and final discharge may be many minutes.

If the end B is to earth when contact is made at A (Fig. 40), then the potential at F will sink instantly to near A, then gradually rise to H. The lines of potential will, as before, for the same reasons, have their concavity upwards, and the curvature will constantly decrease, showing that the current flowing out at B is constantly increasing, whilst that entering at A is constantly decreasing until the line of potential becomes H B, indicating that the current issuing at B has become equal to that entering at A; or, in fact, the line has become fully charged, and the current is constant and permanent throughout the circuit. This is the state, called by the French "*l'etat permanent*," and the charge in the wire represented by the triangle A H B is called by some electricians the "dynamic" charge, in contradistinction to the charge in a wire with the end insulated, for which the term static is reserved. When the wire, having arrived at the permanent state, has the end A put to earth (Fig. 41), then a portion of the dynamic charge rushes out at that end, A, and the remainder continues to flow out at B. Thus, at the end A a current in the reverse direction to that produced in charging is produced, and is commonly called "the return current." This current is very strong at first, for it has the potential A H for electromotive force, and *no* resistance to oppose it. The current further in the wire must be less than that close to, for the same reasons as those mentioned in the case of the discharge of a wire with the end insulated. The point of maximum potential, which at first is at A (the potential being A H), must eventually be last found in the centre of the line C, for if it came to any other point it would indicate that at the last moment a greater current came out at one end than at the other, whereas it is evident that as long as the highest potential is nearer (as it is at first) to one end A, as a

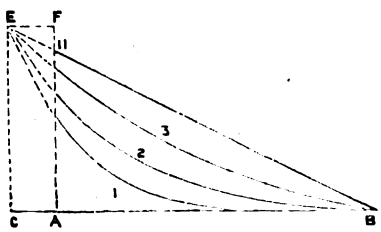

FIG. 40.

greater current is coming out of that end, the currents are consequently constantly tending to equality, and will continue to tend towards equality until they are actually equal, and finally cease at the same moment. Now, as during the greater portion of the time of discharge the currents we have shown is constantly greater at A than at B, it follows that a greater portion of the total charge must pass out at that end. Now, since any electricity at the line of potential at any moment on the B side of the point of maximum potential must pass out at B, and all at the line of potential, that is, at any moment on the C side of the maximum potential must pass out at C, it follows that the path of the point of maximum potential must therefore divide the total quantity of the charge that passes out at A from the total quantity which passes out B. Now, if the path of the point of maximum potential was a straight line from H to C, this would divide the charge into two *equal* parts; but it has been shown that these parts cannot be equal. The path cannot, therefore, be a straight line, but must be a curve

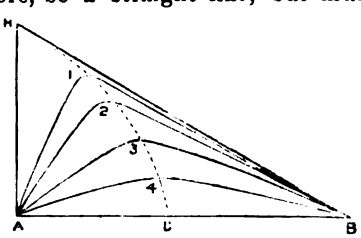

FIG 41.

concave towards A, so as to embrace more of the total charge on the A side of the curve than on the other side. What the exact curve is I am unable to state. Mr. Kempe makes it parabola.

(TO BE CONTINUED.)

NOTICE.—Owing to the great pressure on our columns, we are compelled to leave over a description of the new Elphinstone-Vincent dynamo machine, a notice of the late Mr. Walker, and other matter, for our next issue.

ELECTRIC POWER FOR THRESHING MACHINES.—At Ladenburg, in Germany, on the occasion of a recent meeting of local agriculturists, Messrs. Piette and Krizik lighted up the machine department of the exhibition by means of their lamps, better known under the title of the Pilsen arc lamp, and also drove one of the threshing machines by means of electric power.

CORRESPONDENCE.

"GLOW" LAMPS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I should like to call Mr. Munro's attention to the following definition of "glow," taken from the "Imperial Dictionary":—"To shine with intense heat, or, perhaps, more correctly, to shine with a white heat, to exhibit incandescence. Hence, in a more general sense, to shine with a bright lustre," and to ask him if this is not exactly applicable to a carbon filament in a Swan lamp raised to a state of intense incandescence by a current of electricity?

"Incandescence," as a scientific term applied to a certain effect of heat, must, of course, hold its own, but "glow," as a popular term applied to this new and beautiful light, is prettier, and I venture to think more acceptable. "Glühlampe" is already in general use in Germany.—Yours, &c.,

December 30, 1882. W. H. PREECE.

MISAPPROPRIATIONS BY SCIENTISTS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: The readers of *The Electrician* must have been impressed for some time back, as I have been, with the frequent misappropriations of scientific inventions, and what would seem to be in harmony with the unhealthy tendency of the age, the too frequent very slightest taste of scruple exhibited in the *tour de main*.

Certainly it is unpleasant enough to have, for example, one's clothes stolen, yet to see them worn before our face is a little too much of a good thing, and under such circumstances we need not be surprised to read the very reasonable remonstrances of the real owners.

I had thought that one of the foremost functions of science was calculated to clear away those one-sided, ungenerous principles that actuate so often a section of the lower, mere trading classes, yet if we encroach in the manner we are at present doing upon the sacred domain of science, with all this elbowing and crushing in order to secure one unjust vantage ground or another, the divinity herself will soon be coerced to change her spiritual for a more worldly character, attracting congenial worshippers devoted more to deified mammon than to the generous nature of science.

It is a positive relief, however, to observe at times a frank acknowledgment of merit in others by eminent scientists whose judgment carries weight with it, against the studied silence, or something worse, of men whose interests lie in an opposite direction.

Your able contributor, Mr. Bosanquet, could doubtless afford to recognise the merits of Dr. Paget Higgs's dynamo, in your issue of the 3rd December, but such recognition might have come with equal grace from others more directly interested in the admission.

In fact, the pursuit of science for itself will always maintain a scrupulous regard for a ready acknowledgment of the principle just named, and in this respect no safer guide could be followed than that of Dr. Faraday, whose scientific researches were too sacred to be sullied by either mere mercenary motives or factitious self-glorification.

Yet, looking back upon the history of only two years, and the extravagant prizes prominently held out for electrical inventions, it is not surprising that so much that is done now may be attributable to that cause, and that so much which is neither just nor equitable should be attempted in order to secure a little of the golden fruit that still hangs so temptingly in this garden of Hesperides; nevertheless, as the crop becomes less heavy and valuable, we may naturally look for a return of more honourable treatment, simply because there would be not sufficient inducement to act otherwise.—Yours, &c.,

W. M.

SELF-REGULATING DYNAMO MACHINES.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: The pages of a scientific journal are not, I grant, the proper place for personal controversy; yet I am compelled in self-defence to beg the favour of your insertion of this letter, on the following grounds:—In the first place, in the columns of a scientific journal, Mr. Kapp, under the plea of writing a scientific article, claims on behalf of his friends what had the week before been claimed for myself. I then gave you what I believe to be a true history of the progress of invention in this matter, not advocating, I hope, my own cause pre-eminently. Mr. Kapp now lays claim to the first practical application of an old idea. Will you not agree with me that nearly all the principles involved in the present stage of electric lighting are old—very old? But unless Mr. Kapp can "go back of" mine and others' patents in this country, I fear that his claims will have but small legal right.

I apologise for these personalities, and hope that, as a not infrequent contributor to electric journalism, you will favour me in this single lapse.

There are some remarks made by Mr. Kapp that I would like, in a true spirit of eliciting and perhaps giving information, to be explained explicitly, particularly as Mr. Kapp appears to have given great attention to these matters. He states that, to ensure perfect regulation, a variation of 4 to 6 per cent. of the normal speed of engine must be at command. Although I have not myself found this essential in practice, I should much like to know how it is attained. I have employed some of the best engines, but I cannot with a varying load on the engine maintain such a regularity of speed unless I use an engine nearly twice more powerful than the electrical energy calls for. I am told by a gentleman who has had charge in one of the largest engine factories in this country that I am not alone in my experience.

The effects of the magnetic contra-induction of the armature so very clearly explained by Mr. Kapp have been first described in *La Lumière Electrique* by Marcel Deprez, and perhaps previously to that by A. Breguet. In machines having iron cores to the armature this effect cannot be neglected, but it is much less observable when separated from the mutual induction of the magnet circuits than when these circuits are wound together. At the present stage of electric work, however, I should be surprised to see any maker putting iron into his armature where that armature has to carry over 100 amperes, not so much on account of the loss of efficiency in working as for the reason that the machine must become very cumbrous and costly to make.—Yours, &c.,

PAGET HIGGS.

[We have received other letters on this subject, one of which, from Mr. J. E. Jackson, manager of the Electric Carbon, Storage, &c., Company of Scotland, seems to require from us a little explanation. Our valued correspondents, Dr. Paget Higgs and Mr. Jackson, both admit that their work in connection with compound machines was practically a secret. We in the ordinary course of our labours came across a compound machine made by Messrs. Crompton. Our enquiries failed to elicit the name of any other maker. We waited for some months, hoping some one would give us an opportunity of going into the description of such machines, for it must be recollected that much of our information is for a time confidential. The article of M. Bosanquet gave the opportunity, and we urged Mr. Kapp to describe the compound machine. Probably Mr. Kapp knew as little as we did of Dr. Higgs's work, or we are sure he would have been the last person to have attempted to detract from any man's claims to priority. He could only describe the machine he had studied thoroughly, and give the credit to Messrs. Crompton's firm for constructing such machine. It is a fact that Messrs. Crompton have machines in the market of this type, and that no other maker has. We think Dr. Paget Higgs and Mr. Jackson are to blame for not doing as other well-known men do, taking some members of the technical press into confidence, and putting out of question once and for all claims to priority, by a suitably-worded paragraph which records but does not enter into details. Mr. Jackson states that one of their compound machines has been working in England since last April. This is sufficient for the facts of the case, and now we hope readers will turn from personalities to science.—ED. *E.*]

THE ELECTRICIAN.

TO CORRESPONDENTS.

All letters intended for insertion in THE ELECTRICIAN, *or containing questions, must be accompanied by the name and address of the writer, not necessarily for publication, but as a proof of good faith. No notice whatever will be taken of anonymous communications.*

All communications to be addressed to 396, *Strand, London, W.C.*

We cannot undertake to return drawings or manuscripts, and must, therefore, request Correspondents to keep copies.

SUBSCRIPTIONS.

THE ELECTRICIAN *can be had, by order, from any newsagent in town or country, at the various railway stations; or it can, if preferred, be supplied direct from the office, on the following terms (paid in advance):—*

Quarterly	4*s.* 10*d.*
Half-yearly	9*s.* 9*d.*
Yearly	19*s.* 6*d.*

P.O. Orders to be made payable to James Gray, at West Strand Post Office.

NOTICE.

VOL. IX. of THE ELECTRICIAN,

STRONGLY BOUND, WITH COPIOUS INDEX,

NOW READY.

Price 10s. 6d.

CASES FOR BINDING ALSO READY. Price 2s.

Order of any Bookseller or Stationer.

1882.

As usual at the commencement of a new year we take a prospective and a retrospective glance at those incidents most likely to interest our readers. We permit ourselves at this period to break through the ordinary rules of etiquette, and to write about "ourselves." The welfare of the greatest number is supposed to be *the* aim of politicians, and even more so of newspapers. Sometimes the greatest number degenerates into a small numerical quantity, and signifies number *one*. It is but natural it should be so. Yet in our case we are vain enough to think our friends will absolve us from the sin of thinking more of ourselves than of our readers. We have endeavoured to make *The Electrician* not only equal to, but better than any other electrical paper in existence. A little has been done to carry us towards the ideal, much remains to be done. That we have succeeded in some measure is the knowledge that keeps us from slackening our efforts. We are proud to think we have the largest circulation of any old-world electrical paper, we are still more proud of the class of readers who favour us, and we maintain it is the most influential that any class paper has under the sun. Do not our readers think so? There is a small section of our readers that we admire. It is a section whose earnest efforts give a far greater publicity to our notes and to many of our articles than we ever contemplated. These people are more accustomed to wield the paste and scissors than the pen, and we presume it is due to their lack of familiarity with the latter auxiliary that they so seldom mention the title of the paper to which they are indebted for their matter. These are the good, upright, and honest English and American editors whose anxiety for the welfare of the greatest number is so intense as never to permit them to be satisfied that *number one* is in the right position to enable them to turn their attention to number *two*.

We shall not trouble our readers with many details of what we hope to do during the coming year; we may, however, mention that to the list of English contributors we are adding the names of the most prominent among the men of science in America, and shall endeavour not only to detail the results of progress in England, but also in America. The labours of Bell, Brush, Edison, Maxim, &c., have shown us that our cousins are eager and forward in the applications of electricity, and further, their citizens are earnest in the support of new inventions. We cater for the English-speaking race, and not for a particular portion of it.

The most important work of the year has been the passing of the Electric Lighting Act during the last parliamentary Session. The thanks of all interested in the progress of electric lighting are due to Mr. Chamberlain for his perseverance, in the face of difficulties, to get this Act passed. The Act puts a good deal of power into the hands of the Board of Trade, but to no greater extent, probably, than in the case of railway and other public matters. The Board of Trade has framed rules to be followed in the granting of licenses and provisional orders. We have so recently dealt with the draft provisional orders lodged in compliance with the Act and rules, awaiting the decision of Parliament, that we do not propose to deal further with this part of the question. The immediate progress of the electric light depends upon these provisional orders. Isolated installations may be made here and there; but little of a satisfactory nature will be done till it is shown that electricity can be distributed as easily and with greater safety than gas. The public are not unaware of the advantages of a pure light, and shop keepers of almost all kinds will welcome a light that in no way vitiates their goods—whilst sanitarians point out the benefit that must arise from the non-vitiation of the atmosphere. Gas companies, however, need not fear—gas is too valuable a product of manufacture for a variety of purposes to be put aside, and this applies, perhaps, more especially to its use as a heating agent. Twelve months ago it was hoped that reservoirs of electricity had entered upon a practical stage; and so they had to a certain extent. The public, however, had conceived a totally erroneous opinion about storage or secondary batteries—nor has a healthy tone yet been found. Dr. Lodge, Professor Gladstone, and Mr. Tribe have carefully studied the problems found in secondary battery work, and have published their conclusions, the one in the pages of our contemporary, *The Engineer*, the others in papers to *Nature*, and to the British Association. The Sellon-Volckmar secondary battery is said to have been greatly improved during the year, and to be

Digitized by Google

now in a state bordering on perfection. The FitzGerald-Crompton battery is, we understand, to be manufactured by Messrs. Crompton and Co. on a practical scale. Several of the companies who have applied for provisional orders are, we are informed, determined to try the storage system on a large scale, and we have no doubt will succeed if they can but grasp the problem aright. We are pretty well convinced that as yet electric light engineers hardly realise what they really want. M. Jablochkoff is said to have a good storage battery, in which sodium plays a prominent part. The arrangement is by no means new—it has been known for a long time—but previous investigators have seen the uselessness of attempting to use materials at once scarce, dangerous, and costly, the first property being really the most disadvantageous.

With regard to lamps, whether incandescent or arc, there is but little new to chronicle. The resistance and the radiating surface of the best known lamps are, perhaps, only tentative, inasmuch as experiments are being constantly made to increase the candle-power obtained per indicated horse-power. We still hold to the opinion that most of the incandescence lamps will sooner or later be made with similar resistance for a given radiating surface, and with universal contacts, so that they can be used like gas nipples, and the lamps will be obtainable from any shop, as are gas fittings. The idea which seems so much in vogue at present of appointing sole agents here and there for certain districts is not good. If electric lighting becomes general, the lamps should be obtainable at any china or glass warehouse, or even at every ironmonger's. Thus far we have spoken of incandescent lamps, and just as improvements are being continually made in them, so also in arc lamps. The improvements are minor improvements in detail, and, so far as we know, there has been no new principle utilised. The Pilsen lamps are coming more into favour; but, otherwise, the lamps of Crompton, Brush, and Brockie are those principally used. Designers are aiming at simplicity of construction, certainty of action, and cheapness of price.

The past year has seen the machines of Gordon and Ferranti completed and exhibited. These, as has already been explained in detail in our columns, are alternate current machines, and do not generally meet with the same amount of favour as continuous current machines. The charging and discharging of electric light cables under the action of alternate current machines has not been considered so fully as the charging and discharging of long telegraph cables. It will, however, have to be considered when large installations are in question, and the time function must then be taken into account. We have heard of large continuous current machines under trial, but, as yet, they are not in a sufficiently advanced state to be made public. A decided step in advance has been made at the works of Messrs. Crompton in the production of the compound machine. It is needless to say more of this machine here as it has been so much referred to lately in our other columns. Whatever credit is due to the manufacture of such machines must undoubtedly be given to Messrs. Crompton, that firm being as yet the only makers for sale of this class of machine. Examples of the Chertemps-Dandeu, and of the Jablockoff machine have been exhibited during the year, also of the Elphinstone-Vincent machine, the latter of which has met with a good deal of favour, and is likely to have a fair future if its performances are at all comparable with the statements we have heard.

Before dealing with the work of individual firms, it will, perhaps, be well to look at the speculation of the year. The following statistics are taken from a list of the principal new companies brought out in the year, prepared by Messrs. Spackman and Sons, of 3, Great Winchester-street Buildings. The complete list was given in *The Times* of January 2:—

Name of Company.	Capital authorised.	Capital offered.	Amount of Shares.	Deposit.	Total Deposit.

Yorkshire Brush Electric Light & Power (L)	300,000	200,000	2 0 0	2 0 0	200,000

A number of these companies are already in the hands of the liquidators, and others must follow. An installation here and there of fifty or a hundred lamps will not pay current expenses, and as concessions are of the past, shareholders will ere long demand a searching investigation. Most of these companies have a nominal capital sufficient for one, two, or more large installations. By large, we mean designed to supply a whole town, and our advice would be to select a town or towns, agree with the local authority, and use the capital in a manner similar to that in which capital is used in a town gasworks. The distribution of electricity will follow on similar lines to the distribution of gas. Only rich men and large works manufacture their own gas. Such little gasworks do not pay in a commercial sense, nor will small electric light installations of that kind pay commercially. These works pay well the manufacturers in iron, of gasometers, and so on, and so do small electric light installations pay builders of engines, dynamos, &c. The electric light companies are not formed to build engines or dynamos, &c., but to distribute light; but if they should follow in the footsteps of the "jack of all trades," we forsee a still greater fall. Enough of companies. We are not concerned to find a way out of their difficulties for shareholders; they put shackles around their necks in spite of advice to the contrary, and are now beginning to realise in a wholesome manner that a "burnt child dreads the fire."

The three incandescence lamps of any repute are those of Edison, Maxim, Swan, in alphabetical order. Of these the Edison and the Swan are the most prominent. Large installations of these systems are in contemplation, in progress, or complete.

Edison.—The two largest installations of Edison lamps during the year are those at the Holborn-viaduct, and at the Brünn Theatre. The arrangements at both these places have been more or less completely described in our paper. We may say, however, that a third large Edison machine has recently been sent from America, and will shortly be fixed at Holborn. This is a thousand or twelve-hundred light machine, while those at Brünn are only two hundred and fifty light machines. According to the accounts that reach us from Brünn the lighting is very successful, and has attracted a very large number of interested visitors. It may be granted that the Edison Company has been the first to establish a central station for the distribution of electricity for incandescent lighting to all classes of consumers, and the registration of the consumption by meter. The station at Holborn-viaduct was intended to show the practicability of supplying electricity in a manner analogous to that universally adopted in the case of gas. The company has complied with the necessary forms, and has lodged provisional orders which, if granted, will enable them to set about the work of supplying a far more extended area than that at present covered by them. The experience gained since the starting of the Holborn station, in regard to the fundamental requirements of this class of installation and the practical difficulties to be overcome, has been very valuable, and the company believe that when an adequate area shall have been covered with the requisite conductors, and the various improvements suggested by experience introduced, the central station system of electric lighting will be fairly and successfully able to compete with gas lighting, and will prove remunerative even when competing with gas at the present London prices. This company has made a number of isolated installations for public buildings, factories, ships, &c. We are glad to be able to exonerate this company from any attempt to transact business upon false principles and at unremunerative prices. We believe both the Edison and the Swan companies to be carried on with strict regard to the "bawbees," and every effort is made to obtain a fair return for the capital invested. That there have been a few minutes or hours when darkness held sway over the lamps should not bring adverse criticism; rather we should think the pioneer central station installation in England has been fairly successful, and understand that the experience now gained will greatly lessen the chances of failure. We must confess that we look upon secondary batteries as the source by which to obviate such accidents. A battery that would regulate and store for an hour's supply would be found to be invaluable. Electric light engineers do not, or will not realise this. The Edison Company have reduced the price of their lamps by some 40 per cent. during the year, viz., from 5s. to 3s. Mr. Edison has personally been as active as ever, and has, perhaps, more than ever patronised the Patent Office. It is expected his more recent improvements in machines and lamps will greatly increase their efficiency and economy.

Messrs. R. E. Crompton and Co. have been probably more energetic and more successful than any other firm in introducing the electric light. Not only has the business of the firm greatly increased, necessitating a large extension in their shops at Chelmsford, but they have, in addition to their own work since the formation of the Swan United Company, contracted for and carried out some of the Swan United Company's most important installations; in fact, in speaking of the work of the firm we are compelled to speak of that of the company. A new firm (Messrs. Crompton, Winfield, and Co., of Birmingham) has been formed to manufacture the fittings, &c., necessary for electric light work. Messrs. Crompton and Co. have carried out a large number of installations, among which we may mention the following, where Crompton arc lamps are used:—Messrs. Tate and Sons (Liverpool), Messrs. Vernon and Ewens (Cheltenham), Messrs. Fox and Sons (Staincliffe), town of Dewsbury, Messrs. Littlewood; J. Mackay, Esq.; Cardenosa and Co. (for Spain), Mathewson and Co. (for Egypt), Dahl Brothers (Copenhagen), Johnson and Phillips, Davis (Derby), Kirkham (Russia). Additional lamps have been supplied to Risca Colliery. The Bürgin dynamo manufactured by this company has found many admirers, being used by Mr. Lever (Bowden) the inventor of an arc lamp, the Faure Accumulator Co., the Maxim Weston Co., the Telegraph Construction and Maintenance Co. for exciting the Gordon machine, &c. Installations of the Swan incandescent lamps have been made for W. P. Hope, Esq., Messrs. Johnson and Phillips, P. Jones, Esq. (Chelsea), Messrs. Morewood (Llanelly), and the Steam Yacht "Empress" has been fitted with these lights. Messrs. H. Bennett and Co., of Glasgow, have given orders for six installations of Crompton arc lamps, while Messrs. Norman and Sons (Barrow-in-Furness) have required eight sets of apparatus—

Digitized by Google

some for arc some for incandescent lighting. At various times we have mentioned the work being carried out through the agency of Mr. J. H. Greenhill (Belfast), who has had installations at Messrs. Hall and Co. (Cork), Messrs. Guiness, Son, and Co. (Dublin), Messrs. Harland and Woolf (Belfast), Messrs. D. and W. Carmichael, Messrs. Shaw and Sons (Limerick), and for A. R. Walker, Esq. (Newry). The harbour at Fraserburgh has been lighted with arc lights to the order of Mr. Mavor (Glasgow). At the late Munich Exhibition we had the pleasure of meeting Mr. H. Bollinger, to whose order Messrs. Crompton have supplied nine installations for places in Italy and South Germany. At the time, we noticed the lighting of the Birmingham Town Hall for the musical festivals, and besides this the firm of Crompton, Wingfield, and Co., have carried out several installations in and around Birmingham.

The Swan United Company.—As we have stated, many of the installations just referred to consisted of Swan incandescent lamps, and, therefore, besides supplying their own work, the Swan Company manufactured the lamps required for the completion of these orders. The Company has also carried out other works, either through Messrs. Crompton or their own engineers. Thus the former have extended the electric light, twenty arc lamps and three hundred incandescent, through the whole of the General Post Office buildings at Glasgow; also have carried out so far the work at the new Law Courts, where some 450 Swan lamps are now fixed; have extended the work at the Nine Elms Station of the South Western Railway, where 28 arc lamps are now used, as well as the work at Messrs. Laing and White's, of Holborn. The Swan Company has fitted Swan lamps in H.M.S. "Himalaya," in the "Wairarapa," and a sister vessel, belonging to the Steamship Company of New Zealand, in the "Goorkha" and "Rena," belonging to the British India Steam Navigation Co.; in the "Lonsdale," "Cephalonia," and "Pavonia," belonging to the Cunard Steamship Company. The houses of O. E. Coope, Esq. (Berechurch Hall); Captain F. Markham (Penrith), Sir M. W. Ridley (Plessy), J. H. Gartside, Esq. (Manchester), and Mr. Bouron (Edgware-road) have been lighted with these lights, as have the shops, factories, or mills of Messrs. Edmundson (Westminster), Messrs. W. Moore and Sons (Isle of Man), Messrs. Rowntree and Sons (Scarborough), and Messrs. Coxon and Co. (Newcastle-on-Tyne). The light will be found at the Royal Institution. Many of the machines used in these installations are those of Messrs. Siemens. We may state here that Messrs. Siemens seem to have decided to manufacture and supply rather than to undertake lighting, and hence we shall be unable to chronicle lighting work carried out by this eminent firm under the title of that firm.

Engines.—This is not the title of a firm, according to Artemus Ward, but according to our ideas the word may be used as a heading, and we may digress for a moment. With certain exceptions the builders of engines seem to be utterly indifferent to the bringing of their wares to the notice of electric light people. They seem to think that everybody must necessarily know their particular firm, inasmuch as they advertise regularly in certain technical papers. We not long ago had occasion to remark on the ignorance of the eminent writers in the *Saturday Review*, and were surprised shortly after to find many eminent electricians ignorant of the standing of some of the firms of engine builders. The business of engine builders for the next few years in connection with electric light work will be enormous. We are often asked concerning these said builders, and may for once take the occasion to mention a few whose work can be trusted. From inquiries made, we are told that engines built by Marshall and Sons are thoroughly good. Messrs. Crompton have used a number of them, and the men like the engines. The same firm has recently, at Berechurch Hall, tried an engine by Messrs. Davey, Paxman and Co. (of Colchester) who are said to turn out thoroughly good work. Two other engines by this firm are to be used at Nine Elms. When room is an object Hodgson's rotary engine will be found worthy a trial. The engine on the Thames Embankment, by Ransomes Head, and Jefferies, has done good work, and is well spoken of by the Jablochkoff Company. Mr. Hindley, Bourton, Dorset, is giving great attention to engines for electric light work. There are many other well-known makers, but they do not think it necessary to trouble us with any facts concerning their work, which neglect, it may be, does not hurt us. Those engine builders who are alive to the wants of the time during the next few years, and keep themselves thoroughly acquainted with the requirements of electric lighting, designing machines accordingly, doing good, trustworthy work, will reap a rich harvest. Fixed, semi-fixed, portable engines—all are required, and will be, till the forces wasted by nature are harnessed to supply our wants.

The Hammond Company.—During the past year the Hammond Electric Light and Power Supply Company have thrown themselves very thoroughly into the work connected with town lighting, in order to pave the way for obtaining a share of the work of corporations when powers are obtained under the Electric Lighting Act. At Chesterfield they have continued the lighting of the whole town with Brush arc lights and the Lane-Fox incandescent lamps upon the same circuit. While the Brush lights have given great satisfaction, the Lane-Fox lamps have been almost universally condemned; but during the last month a very great improvement has taken place in this lighting, due to the supply of a greatly improved Lane-Fox lamp, and at the present time this installation is in a much more satisfactory state than it was a year ago. A large town installation has also been made by this company at Brighton, where now about 50 Brush arc lights are running from their central station. Town lighting was also done by this company during the exhibitions at Peterboro', Worcester, Tynemouth, and Bradford. Various extensions have been made to the plant previously erected by them. At McClure's, of Stockport, a 16-light apparatus has been exchanged for a 40-light apparatus. At Leslie's, shipbuilders, Hebburn, also, a 16-light apparatus has been exchanged for a 40-light apparatus. R. and W. Hawthorn, Newcastle, have taken 16 more lights; Edwards and Sons, Newcastle, 16-light installation; Palmer's Shipbuilding Company, Jarrow, 16 more lights; Stanner's Close Steel Works, Workington, 16 lights. This company undertook the lighting of the Mersey Tunnel, but the working of the Lane-Fox lamps there was not very successful. A town installation has also been made by them at Cockermouth and Portsmouth. The greatest effort, however, that has been made by this company during the year has been to acquire the Ferranti machine, which they think is by far the best machine in the market. One of these machines has already been erected at the works of Messrs. Copestakes, Hughes, and Crampton, at Nottingham. A machine to run 5,000 lights, and weighing about two tons, is on the point of being finished, and if this works with the efficiency claimed for it the company may have reason to be proud of their acquisition. Applications under the Electric Lighting Act were made by the company for every borough in England, but the company have dropped their applications, hoping to secure orders to become contractors for the work of corporations.

Next week we shall refer again to electric light work; meanwhile, we must not forget our old friend the telegraph. Last year most of our review of telegraphic work was relegated to the second week, but we feel it is deserving of a better fate. We find, however, that even now our space is filled, and part of what we have to say must be left for the future. Then, as land telegraphy had first place last time, we will now put cable work first, briefly glance at the lines laid, leaving details to follow. The giant cable company is the

Eastern Telegraph Company.—This company has during the year extended its connections by means of the Malta-Tripoli cable 204 miles in length, the Trieste-Corfu cable 504 miles in length, and the Alexandria-Port Said cable 153 miles in length, giving a total of 861 miles of cable laid in the year. The company has a total system of over 17,000 miles of cable, besides over 1,500 miles of land lines. Its connections—the Eastern and South African Company and the Black Sea Telegraph Company, have respectively 3,858 miles and 350 miles of cable, the latter having 27 miles of land lines. A continuation of the Eastern Company is the Eastern Extension Company with nearly 10,500 miles of cable and 24 miles of subterranean land lines. The total cable system belonging to these companies comprises, then,

Digitized by Google

some 31,704 miles of cable, with 1,590 miles of land lines. The system ramifies to all places of note in the Mediterranean, Egypt, the Red Sea, South East Africa, India, China, Australia, and New Zealand. The oldest cable in the system is the Flinders-Tasmania cable, 180 miles in length, belonging to the Eastern Extension, which was laid in 1869; several long cables of the Eastern and also of the Eastern Extension were laid in 1870, and these cables, to use an old-fashioned phrase, are as good as new.

THE TELEGRAPH CONSTRUCTION AND MAINTENANCE COMPANY.—The cables above mentioned as being laid by the Eastern Company were manufactured and laid in their bed by the Telegraph Construction and Maintenance Company. Besides these this great cable manufacturing company has manufactured and laid the Grietsill-Valentia cable to connect Germany to America, *viâ* Valentia—a cable over 841 miles in length; the Ceara-Maldonado cable, about 403·5 miles in length; the duplicate Madeira-Lisbon cable, over 568 miles in length; and the Lipari-Salina cable, 7·25 miles for the Italian Government. The manufacture and laying of new cables is, perhaps, among the least onerous work of this company. They are so careful to have everything done in the best possible manner, to neglect no precaution, and every man is so thoroughly imbued with the capability of everything and everybody that success in manufacture and in laying are taken as matters of course. If possible, more pride is taken in the ability of the company and the company's staff to pick up and repair cables than in the primary operations. The task of repairing, especially in deep water, is no child's play; but so well arranged is the work that success is hardly ever doubtful. The spirit evidently exists that Napoleon I. so greatly admired—the spirit which will not let one know when he is beaten. There is no retreat, when work is undertaken it has to be done. The vessels and staff of the company have done some notable repairing work during the year. In the early part of the year the "Kangaroo" repaired the 1874 Atlantic cable near Newfoundland. The North Sea cables, that suffered so severely as to cause a block to continental communication, were repaired. The shore end of the Brazilian Company's St. Vincent-Pernambuco cable was replaced. The Ceara-Maldonado cable, above-mentioned, is a new section of the Western Brazilian Company's system added to the old system, by cutting the cable and adding this new piece. The most notable repair, however, was one by the "Seine," mentioned by us at the time, to the Porthcurnow-Lisbon cable, off the coast of Spain, in a depth of between 2,000 and 3,000 fathoms of water. The "Scotia" accomplished the task of repairing the Brest St. Pierre (1869 Atlantic) about mid ocean. In the course of the repairs, or rather of the sounding, the bottom of the Atlantic was found to be exceedingly rocky and precipitous, varying within a short distance from 990 to 2,300 fathoms. The cable had been frayed, evidently from contact with edges of rocks. A peculiarity during this work was that the old cable was several times brought successfully to the surface, showing that, generally, its strength was unimpaired. The work of repair was successful. Several new lengths of cable were used, and the cable rendered thoroughly efficient. After laying the duplicate Lisbon-Madeira cable, a new shore end was placed at Lisbon. During the laying of the duplicate cable a new shoal was found, not previously entered on the charts. The water shallowed rapidly from 2,400 to 100 fathoms, and the shoal necessitated the laying of the cable a little out of the direct course. The shoal is now marked as the "Seine." It is singular that a similar shoal, known as the "Gettysburg," was found during the laying of the original cable, and caused a divergence in the laying of that cable from the most direct route.

It will be seen that the company has done a good deal of good work during the year.

Next week we shall refer to the cable work of the Silvertown Company.

POST OFFICE TELEGRAPHS.—For the inland telegraph system under the control of Her Majesty's Post Office the year 1882 has been a prosperous one. An increase of £170,000 upon the message receipts is reported, as compared with the preceding year. To meet the augmented traffic which this sum represents, the additional wires which were erected in 1880-1 have had to be supplemented by duplex and quadruplex circuiting. Several additional circuits of the latter kind, and a great number of the former, have been introduced during the past year, adding immensely to the capacity of the wires, and proving beyond all doubt the capabilities of the inland service for dealing with even a still greater increase of business. Indeed, it has been found that the more facilities the department offers, and the greater the efficiency and expedition with which it disposes of the traffic, the greater is the amount of patronage it receives. This is conspicuously the case with news messages, the increase upon which has grown so enormously that the night service between important centres of the kingdom is now almost, if not quite, as heavy as the day service. A vast number of new circuits have necessarily been opened to accommodate the wants both of the Press and the general public; but this, as we have already explained, has been effected for the most part without any great outlay in the shape of extensions. Extensions, however, in respect to another branch of telegraph business have taken place, and this to a considerable extent, namely for the purposes of Telephonic Exchanges. This class of business has been largely developed under the auspices of the Post Office, especially in the Northern Counties—Newcastle, Sunderland, Hartlepool, Middlesbro', Hull, and Bradford being places that may be named as now adequately provided in this respect. The Telephone Exchange system established in Newcastle is especially worthy of mention as perhaps in all respects the most complete and perfect system to be found in any town in the kingdom, or perhaps outside of it either. In the South and West of England, similar exchanges have been established at Newport, Cardiff, and Plymouth, as also in the Midland Counties, notably at Leicester. The system is rapidly growing in public favour, and it will be probably extended to other towns and districts as circumstances may seem to warrant.

STUDENTS' COLUMNS.

CITY AND GUILDS EXAMINATIONS.

[*These answers are intended to guide, to give information and references, to put the student in the way of getting information, and* NOT *to give the exact answers that should be written in an examination.*]

The solutions in this number are alternative solutions to some of the "*Honours*" questions in the paper hitherto considered, by E. C. RIMINGTON, Esq. (School of Electrical Engineering), 12, Princes-street, Regent-street.

1, 2, and 3. The same as in the "*Pass*" examination.

4. Draw the "characteristic curve" of a dynamo, and explain what are the various practical uses that can be made of it. Explain in detail the various experiments you would carry out to enable you to draw the characteristic curve of a special machine.

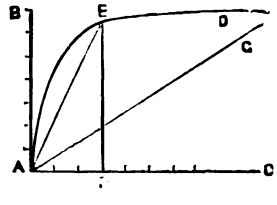

FIG. 1.

Ans. The axis A B represents the E.M.F., the axis A C represents the current. The total resistance required to give any current, A F, when the dynamo is running at the speed for which the curve is constructed, is equal to $\frac{E}{C} = \frac{E F}{A F} = \tan E A F$.

The internal resistance of the dynamo is, of course, constant,

Digitized by Google

and can be represented by the tan of an angle G A C. The practical uses of a characteristic curve for a dynamo are that, if we require a given current, we can obtain the resistance in the external circuit necessary to obtain that current, or *vice versâ*.

To find the characteristic curve for a dynamo at any given speed, note the total E.M.F.'s of the machine and the currents corresponding to each total E.M.F. From these co-ordinates a curve is to be constructed.

In practice we should take the E.M.F. at the terminals of the machine and the current flowing at the same time, making, say, twenty observations and varying the external resistance at each observation. If we multiply the E.M.F. at the terminals by the total resistance in circuit and divide by the external resistance, we obtain the total E.M.F. of the machine; now mark off on the axis A B distances to represent the total E.M.F.'s in volts on a convenient scale, and on the axis A C mark off distances corresponding to the current in amperes on the same scale. Draw the ordinates from the corresponding E.M.F.'s and currents, and from the points thus obtained construct a curve.

It is often convenient to draw the divisions representing amperes larger than those representing the E.M.F. in volts. To find the characteristic curve for any increase or decrease in speed, we have only to lengthen or shorten the ordinates representing the E.M.F. in the ratio that the new speed bears to the former, and then to draw a fresh curve through these points. The reason for this is that when the current remains constant the E.M.F. increases or decreases directly with the speed. When a characteristic curve has once been constructed for any dynamo for any one speed, we have all that is necessary for determining (1.) What speed to run the dynamo to obtain a given current through a given resistance. (2.) What current we can obtain through any given resistance at any given speed. (3.) What resistance we shall require to obtain any given current at any given speed.

5. Draw the "characteristic curve" of a magneto-electric machine, and compare the advantages and disadvantages of dynamo and magneto machine.

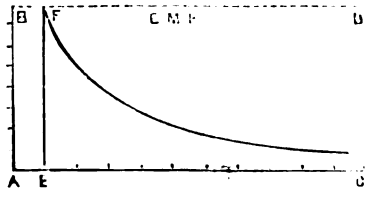

FIG. 2.

Ans. The axis A B represents the current in amperes, the axis A C represents the total resistance in ohms. A E represents the internal resistance, and E C the external. The E.M.F. is practically constant for any fixed speed, and can be represented by the line B D.

Although we may take the E.M.F. of a magneto machine running at a fixed speed as practically constant, it is only approximately so, for the less resistance we have in circuit the greater the current in the armature coils, and this current, acting inductively, tends to neutralise that flowing round the field-magnets, and thus, by diminishing their magnetism, to reduce the E.M.F. of the machine.

The E.M.F. being practically the same is a great advantage when the external resistance is variable, as a greater steadiness and regularity is obtained. In a dynamo, when the external resistance increases, it not only reduces the current, but also the E.M.F., by weakening the field magnets, where in the magneto the current would simply vary inversely as the total resistance. One disadvantage attending the use of the magneto machine is that it requires a separate dynamo to excite it, but where a number are at work of similar dimensions and construction we can employ one dynamo to excite the rest.

6. Given the "characteristic curve" for a dynamo running at 500 revolutions a minute, as well as its resistance, show how you can ascertain at what speed it must run so that a current of 1·3 ampere shall flow through each of 30 incandescent lamps in parallel circuit, the resistance of each lamp for that circuit being 42 ohms?

Ans. Suppose the internal resistance of the dynamo to be 1 ohm.

$$\text{Total external resistance} = \frac{42}{30} = 1{\cdot}4 \text{ ohm.}$$

Current required to work the 30 lamps $= 1{\cdot}3 \times 30 = 39$ amperes.

E.M.F. required to give 39 amperes through a total resistance of 2·4 ohms = 93·6 volts.

Find where the ordinate from the division on diagram corresponding to 39 amperes cuts the curve; this will give the E.M.F. at 500 revolutions, corresponding to a current of 39 amperes, let us say 67 volts.

Then, 67 : 93·6 :: 500 : speed required,

$$\therefore \text{required speed} = \frac{500 \times 93{\cdot}6}{67} = \text{about } 700 \text{ revolutions per minute.}$$

7. How does a "shunt dynamo" differ from a "series dynamo?" Explain fully their relative advantages and disadvantages. Give examples showing the resistances you would employ in each case for the field-magnets and for the armature.

Ans. In a series dynamo the current generated in the revolving armature flows out at one of the brushes round the field-magnets, then through the external circuit, and back again to the other brush. In the shunt dynamo the current generated in the armature divides at the brushes, and flows partly through the external circuit and partly round the field-magnets, the resistance of which is high compared with that of the external circuit. In an ordinary dynamo the E.M.F. is greatest when the machine is short-circuited, in the shunt dynamo when the external circuit is open.

The shunt machine is exceedingly useful where we have a varying external resistance, such as a number of incandescent lamps arranged in parallel circuit, because the greater the external resistance is the more current flows round the field-magnets, thus augmenting the E.M.F. Thus, with a shunt dynamo, it is possible to reduce the number of lamps in parallel circuit down to one; but, to keep the E.M.F. at the terminals constant, we have, of course, to diminish the speed, while with a series dynamo, as we reduce the number of lamps the E.M.F. falls, and to maintain it constant we must increase the speed. Machines are now constructed combining the series and shunt methods of winding the field-magnets, so that the E.M.F. remains constant without altering the speed when the external resistance is increased or diminished within certain limits. In a Siemens shunt dynamo the resistance of the armature is ·4014 Siemens units, and the resistance of the field-magnets is 4·46 Siemens units, while in a Siemens dynamo of corresponding size, the armature being of the same resistance, the field-magnets have a resistance of ·3065 Siemens units.

8. Define an ohm, a volt, an ampere, and a coulomb. A certain magneto-electric machine, with an armature of $\frac{1}{2}$ an ohm resistance, from brush to brush, running at 800 revolutions a minute, produces an electromotive force of 30 volts, what current would this machine send through a wire having 1,000 ohms resistance, if the armature were wound so as to have 5 ohms resistance, and were revolved at 1,300 revolutions a minute?

Ans. An ohm is the practical unit of electrical resistance, or the reciprocal of conductivity, and is equal to 10^9 C.-G.-S. absolute units.

A volt is the practical unit of E.M.F., or the force tending to set electricity in motion. It is the E.M.F. required to produce a current of one ampere through a resistance of one ohm, and is equal to 10^8 C.-G.-S. absolute units.

An ampere is the practical unit of current, and is produced through the resistance of one ohm by a difference of potential of one volt between its ends. It is equal to 10^{-1} C.-G.-S. absolute units.

A coulomb is the unit of quantity. It equals an ampere flowing for one second, and is therefore also 10^{-1} C.-G.-S. absolute units.

The armature having 10 times the resistance would have 10 times the number of convolutions in it if wound with the same sized wire, and at 800 revolutions the E.M.F. would be 200 volts.

$$800 : 1300 :: 30 : x = 487{\cdot}5 \text{ volts.}$$

Total resistance = 1005 ohms.

$$\text{Current} = \frac{487{\cdot}5}{1005} = {\cdot}4857 \text{ ampere.}$$

TRAFFIC RECEIPTS.—The traffic receipts of the Great Northern Telegraph Company in December, 1882, amounted to £17,640. For the period January 1 to December 31, 1882, they were £241,360, and for the corresponding months of 1881 £234,850, against £236,576 during the same period of 1880.

CORRESPONDENCE.

STATIC ELECTRICITY AND QUANTITY.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In reply to Mr. Von Tunzelmann, p. 162, my statement that there is no such thing as a *quantity of static electricity* is not very extraordinary, seeing that, like a good many other people, I do not admit the existence of a quantity of electricity at all, static or dynamic. If electricity is, as I believe, not an entity, but a condition, an action, it cannot be expressed as a quantity. But dynamic electricity is like heat (which also cannot be expressed as a simple *quantity of heats*) in that it has a definite relation to molecules and atoms of matter, and this relation of electricity (as of heat) can therefore be expressed as a quantitative relation or effect.

I wished to draw attention to the fact that such a relation does not exist in what is called static electricity, but which should be called the static actions of electricity. The coulomb is a *quantity* as regards dynamic electricity, but it is a *function* only as to static electricity.

The unit of force is defined to be the force which produces unit of momentum in unit time. But in reply to the question I do deny that there is such a thing as "quantity of force." As with electricity, so with force, there are two ways of regarding it—the natural and the artificial. Mathematicians have, for purposes of calculation, constructed a purely artificial electricity quite different from anything to be found in nature, and the *force* of the mathematician is also an artificial production; very useful, but having no existence. Attraction, pressure, are the true forces, and gravitation is the natural example of them. These cannot be expressed as quantities, but as degrees; to render them expressible as quantities, we have to express them by their effects upon quantities of matter. Now, I am not prepared to admit that measuring an effect as a quantity is really measuring the cause as a quantity. The unit of force is a convenient and necessary measure, but it seems to me that, after all, it is not a measure of force, *i.e.*, not a *quantity of force*, but a measure of energy, the quantity of energy due to a force acting in limited conditions. It is a measure of force, but indirectly.

I do not explain "that by static electricity *I mean* potential energy;" nor can the deduction be drawn that I deny the existence of a quantity of potential energy. It is not worth while arguing a syllogism based upon fictitious resemblances of phrases. I say that what is called static electricity means the existence of conditions in which energy becomes potential, as in a strained spring, I do not see how to express "strained spring condition" as a quantity, but I quite see how to express quantity of energy stored in a strained spring.

I may further say that I do not consider electricity to be "a form of energy," and, therefore, need not argue out the results. I consider it to be a word expressing conditions and phenomena resulting from transfer of energy. I can only say that the point he argues is perfectly familiar to me, as may be seen from the following extract from the second edition of my "Electricity," now passing through the press.

"We not uncommonly hear of the 'conversion of electricity into light, heat, or mechanical energy.' This is an obsolete error, originating in the confusion of the two factors of electricity. Electricity regarded as a quantity calls for two distinct expressions, Q, and Q^2. The first is strictly a quantity, and is that which the old theories considered to be material or analogous to matter, and represented to the mind by the expression, imponderable fluid, but which the new theory considers to be numerical, the action of definite material quantities or molecules. This, which is properly the "electricity," can no more be converted into heat or anything else, than can the water in a steam boiler or hydraulic engine. The second, Q^2 is the electric energy, which is the true cause of electrical phenomena, and which may be converted into heat and work, because it answers exactly to the mechanical energy (also convertible) carried by the water as steam from a boiler, or under pressure in the hydraulic engine."—Yours, &c.,

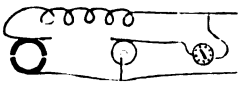
J. T. SPRAGUE.

CURVE OF ELECTROMOTIVE FORCE.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In the article by Mr. Gisbert Kapp on Crompton's Compound Machine in your issue of Dec. 30, a method of estimating the relative electromotive force in different parts of a Gramme ring while in motion is suggested, which recalls an experiment in which I assisted at the Massachusetts Institute of Technology in Boston, U.S.A., in the spring of 1875. The machine under test was a Farmer dynamo (a simple Siemens armature revolving between the poles of an electro-magnet, the coils of which were in the main circuit), and the curve of E.M.F. at different parts of the revolution was obtained by the following method, due I believe to a fellow student, Mr. Samuel Mixter.

A disc of insulating material (here shown in a different position for the sake of clearness in the diagram) was fixed upon the end of the armature shaft, and carried a band of metal in contact with the shaft, and turned over the edge of the disc so as to make contact at a certain point in each revolution with a spring or brush pressing against the edge of the disc. One terminal of the machine was connected to the base of the machine and so to the shaft, and the spring pressing on the disc was connected through a galvanometer to the other terminal of the machine. Thus, at a certain point in each revolution, the galvanometer became connected between the terminals of the machine, and by making these contacts not too short the effect produced by the rapid succession of currents (the normal speed of the machine was 2,000 revolutions per minute) became very nearly that of a continuous current, the needle not having time to swing back appreciably between successive currents. By shifting the position of the disc on the axis, or of the contact spring, successive observations were obtained of the current at different parts of the revolution.



From the results then obtained with very crude temporary apparatus I have no doubt that excellent determinations of the electromotive force throughout the revolution of the armature could readily be obtained by a similar plan from the better machines of the present day, as in them the successive impulses given to the galvanometer (voltmeter) would be a much nearer approach to a continuous current than in the case I have described. Of course the apparatus must be modified to suit each particular class of machine, as in the form above described it is only suited to a single coil armature. With many coils contacts must be so arranged as to include only a single coil at a time while that coil is passing through a particular part of the field. Thus, with the Gramme ring the apparatus would take a form similar to that mentioned by Mr. Kapp. A ring of insulating material should be mounted so as to surround one end of the commutator, the brushes being sufficiently narrowed to admit it, and this ring should carry two contact springs so adjusted as to rest, at any given position of the armature, upon two successive bars of the commutator In this way as each coil in succession came into the part of the field selected the difference of potential between its extremities would be indicated by a voltmeter connected between the two contact springs. The rapid succession of currents would produce practically the same effect as a continuous one corresponding in E.M.F. to the part of the field selected. By shifting the ring successive observations could be taken throughout the circumference of the field. The modifications necessary for other forms of machine will readily suggest themselves to those familiar with their construction.

I have thought it worth while to bring this matter forward more prominently than was done by Mr. Kapp's casual mention of it, as I am not aware that systematic observations of this kind have ever been made upon any of the machines now in use, although it would seem that if made they could not fail to be most instructive, and to serve a very useful purpose in working out the best forms of pole pieces, position of commutator brushes, and other details entering into the design of a machine, as well as in the comparison of different machines; the importance of a proper distribution of E.M.F.

throughout the field being evident, as well as the comparative blindness of attempts to secure it without such experimental aid.—Yours, &c., J. B. HENCK, JUN.

INDUCTION COIL.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Could you inform me what sort of an apparatus I could obtain to regulate the strength of the current of an induction coil which I have finished, the current of which is too strong for that for which I wanted it? And, also, is it possible to ascertain the quantity or resistance of the thick wire in proportion to the fine of an induction coil?—Yours, &c. E. E. M.

Buckhurst Hill, December 30.

CANTOR LECTURES.*

DYNAMO-ELECTRIC MACHINERY.

BY PROFESSOR SILVANUS P. THOMPSON, B.A., D.SC., M.S.T.E.

Lecture I.—The Dynamo in Theory.

By "Dynamo-Electric Machinery," in the most general etymological sense of the term, is meant machinery for converting the energy of mechanical motion into the energy of electric currents, or *vice versâ*. From this wide definition must be excepted machines like the well-known statical induction machine of Holtz, whose action is purely electrostatic. Those machines only are included in the definition whose action is dependent on the principle of electro-magnetic induction, discovered by Faraday, in 1831. It is, however, not quite easy to decide what machines shall be called dynamo-electric machines, because the sense in which the term is used commonly is narrow, and restricted in a manner not quite logical.

The name dynamo-electric machine appears to have been first employed by Dr. Werner Siemens, in his communication of January 17, 1867, to the Berlin Academy, in which he described a machine for generating electric currents by the application of mechanical power, the currents being induced in the coils of a rotating armature by the action of electro-magnets, which were

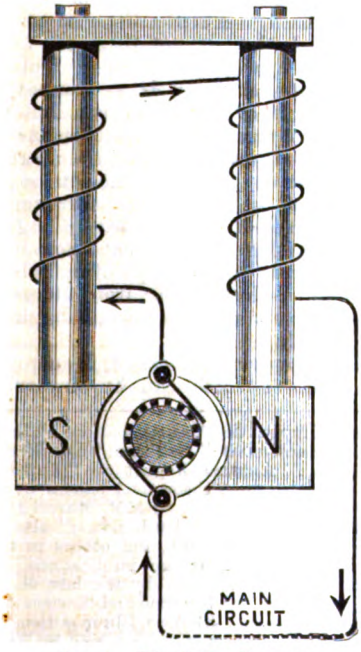

FIG. 1.—The Series Dynamo.

then introduced into electric technology, has not remained thus themselves excited by the currents so generated. The machine was, in fact, a self-exciting dynamo, with the field magnets and armature united "in series" to the external circuit, or what we now call a "series-dynamo," a diagramatic representation of which is given in Fig. 1. But the term dynamo-electric machine, restrained to its narrowest meaning. It was next applied to machines of kindred nature, in which, though self-excited, only a portion of the entire current generated by the rotating armature was applied to excite the field-magnets (see Fig. 2). This principle of working (now known as that of the "shunt-dynamo"), first introduced by Wheatstone, is but a variation of the former arrangement in detail, and no violence is done to the original term to apply it to both cases. In fact, the name was

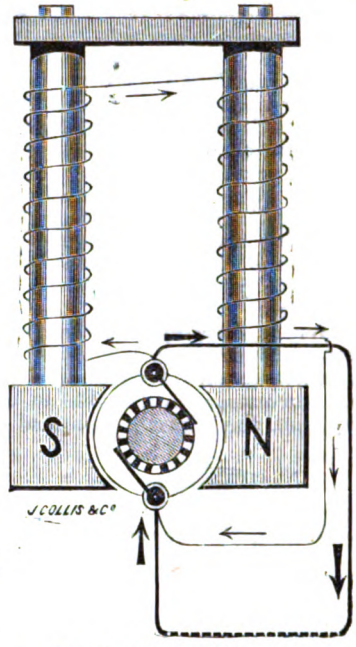

FIG. 2.—The Shunt Dynamo.

welcomed as being convenient in practice for distinguishing such machines from those which were not self-excited—those in which either steel magnets or separately-excited electro-magnets were used to produce the magnetic field.

But since the great development of electric lighting took place, it has been found convenient to use generating machines in certain combinations, in which the self-exciting principle is abandoned. Some systems of electric lights require alternating cur-

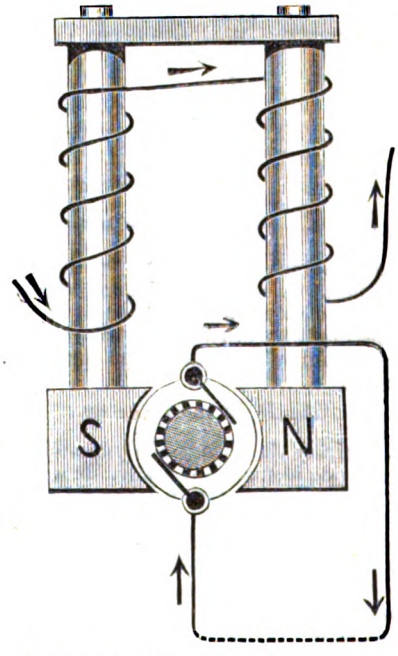

FIG. 3.—The Separately-excited Dynamo.

rents, produced in machines which cannot excite their own magnets with a continuous magnetisation; and there are other systems where continuous currents are employed, in which also practice has shown that the currents are better regulated when the magnets of the dynamos are separately excited by currents derived from an external source. There is, then, a third class of dynamo-electric machine, the "separately-exciting dynamo" (Fig. 3), which was indeed earlier than either of the preceding,

* Reprinted from the *Journal of the Society of Arts*.

Digitized by Google

having been brought out by Wilde in 1866. A dynamo is a dynamo in fact, whether its magnets be excited by the whole of its own current, or by a part of its own current, or by a current from an independent source. The source of the magnetising power is indifferent, provided a magnetic "field" of sufficient intensity be produced wherein the generating coils can be rotated. Now, as it does not matter where the magnetising power comes from, it is clear that we must include amongst possible sources the power of permanent steel magnets. In short, the arbitrary distinction between so-called magneto-electric machines (see Fig. 4) and dynamo-electric machines fails when examined carefully. In all these machines a magnet, whether permanently excited, independently excited, or self-excited, is employed to provide a field of magnetic force. And in all of them dynamical power is employed to do the work of rotating the coils of the armature, in order to generate the electric currents.

The true and comprehensive definition of a dynamo-electric machine is, then, the following:—A dynamo-electric machine is a machine for converting energy in the form of dynamical power into energy in the form of electric currents, by the operation of setting conductors (usually in the form of coils of copper wire) to rotate in a magnetic field.

Inasmuch, however, as every dynamo-electric machine, in the most general sense of the term as now laid down, will work as a motor, and becomes a source of mechanical power when supplied with electric currents, it is possible to discuss dynamo-electric machinery from the opposite points of view in serving

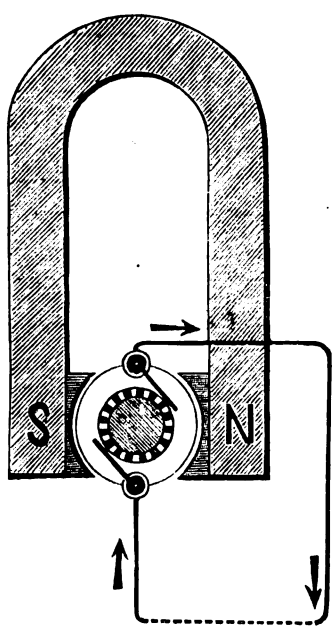

Fig. 4.—The Magneto Dynamo.

the two converse functions, in short, to treat the dynamo on the one hand as a generator, on the other hand as a motor.

It is as a generator only that the action of the dynamo will be considered in the first two of these lectures, reserving considerations respecting its functions as a motor for the third lecture of the present course.

The Dynamo in Theory.

To treat exhaustively the theory of dynamo-electric machines would require not one lecture, but many. It would be necessary, moreover, to enter upon lengthy mathematical and geometrical discussions, which would be out of place in the present course, which is expected to deal with subjects from an industrial, rather than from a purely scientific aspect. The mathematical theory of the dynamo is, indeed, very complex, and takes different forms for its expression in the four classes of machine now included under the one name of "dynamo." For every different variety in each of these classes there is a fresh variety of mathematical symbols. The theory of alternate current machines is entirely different from that of machines which are to furnish continuous and constant currents. Every form of armature and coils requires its own specific treatment in symbols; and the simple consideration of putting iron cores into the coils, when treated mathematically, introduces such complex expressions as to yield no hopes of a satisfactory general solution.

The theory of the dynamo, then, which will be developed in the present lecture, will not be a general mathematical theory. The aim will be to deal with physical and experimental rather than mathematical ideas. A physical theory of the dynamo is not new, though none of any great completeness has yet been given,* most of such explanations being devoted to single machines of some particular type.

It will here be my aim to develop a general physical theory, applicable to all the varied types of dynamo electric machines, and to trace it out into a number of corollaries, bearing upon the construction of such machines. Having recited these consequences, which we shall deduce from theory, it will then remain to see how these consequences are verified and embodied in the various forms assumed by the dynamo in practice.

Physical Theory of Dynamo-Electric Machines.

All dynamos are based upon the discovery made by Faraday in 1831, that electric currents are generated in conductors by moving them in a magnetic field. Faraday's principle may be enunciated as follows:—When a conductor is moved in a field of magnetic force in any way so as to cut the lines of force, there is an electromotive force produced in the conductor, in a direction at right angles to the direction of the motion,† and at right angles also to the direction of the lines of force, and to the right of the lines of force, as viewed from the point from which the motion originates.‡

This induced electromotive force is, as Faraday showed, proportional to the number of lines of magnetic force cut per second, and is, therefore, proportional to the intensity of the magnetic "field," and to the length and velocity of the moving conductor. For steady currents, the flow of electricity in the conductor is, by Ohm's well-known law, directly proportional to this electromotive force, and inversely proportional to the resistance of the conductor. For sudden currents, or currents whose strength is varying rapidly, this is no longer true. And it is one of the most important matters, though one too often overlooked in the construction of dynamo-electric machinery, that the "resistance" of a coil of wire, or of a circuit, is by no means the only obstacle offered to the generation of a momentary current in that coil or circuit; but that, on the contrary, the self-induction exercised by one part of a coil or circuit upon another part or parts of the same, is, in many cases, quite as important a consideration, and in some cases a more important consideration, than the resistance.

To understand clearly Faraday's principle—that is to say, how it is that the act of moving a wire so as to cut magnetic lines of force can generate a current of electricity in that wire, let us inquire what a current of electricity is.

A wire through which a current of electricity is flowing looks no different from any other wire. No man has ever yet seen the electricity running along in a wire, or knows precisely what is happening there. Indeed, it is still a disputed point which way the electricity flows, or whether or not there are two currents flowing simultaneously in opposite directions. Until we know absolutely certainly what electricity is, we cannot expect to know precisely what a current of electricity is. But no electrician is in any doubt as to one most vital matter—namely, that when an electric current flows through a wire, the magnetic forces with which that wire is thereby, for the time, endowed, reside not in the wire at all, but in the space surrounding it. Every one knows that the space or "field" surrounding a magnet is full of magnetic "lines of force," and that these lines run in tufts from the N-pointing pole to the S-pointing pole of the magnet, invisible until revealed by dusting iron filings into the field, whereby their presence is made known, though they are always in reality there (Fig. 5).

Now, every electric current (so-called) is surrounded by a magnetic field, the lines of which can be similarly revealed. To

* See Du Moncel ("Exposé des Applications de l'Electricité," vol. ii.); Niaudet, "Machines Electriques;" Schellen, "Die Magnet-und Dynamo-elektrischen Maschinen;" Antoine Breguet (see "Annales de Chimie et de Physique," 1879). See also some theoretical papers by Clerk Maxwell in "Philosophical Magazine," 1867, and by MM. Marcel Deprez, Cabanellas, de Goarant, and others in the "Comptes Rendus;" also sundry papers by Frölich, Werner Siemens, Hagenbach, and others in the "Elektrotechnische Zeitschrift," and other German publications. Of more general scope is the physical theory advanced by the late M. Antoine Breguet, which deals with dynamos of the Gramme and Siemens type, and of which a detailed summary is given in "Electric Illumination." In an introductory chapter of the same work I have endeavoured to lay the foundation of a more general physical theory. An admirable series of papers on the mathematical theory of dynamo-electric machines, from the pen of a well-known professor of physics, is at present appearing in the columns of *The Electrician*.

† Or, more strictly to the resolved part of the motion in a plane perpendicular to the lines of force.

‡ A more usual rule for remembering the direction of the induced currents is the following adaptation from Ampère's well-known rule:—Supposing a figure swimming in any conductor to turn so as to look along the (positive direction of the) lines of force. Then, if he and the conductor be moved towards his right hand, he will be swimming with the current induced by this motion.

Digitized by Google

observe them, a hole is bored through a card or a piece of glass, and the wire which carries the current must be passed up through the hole. When iron filings are dusted into the field they assume the form of concentric circles showing that the lines of force run completely round the wire, and do not stand out in tufts; in fact, every conducting wire is surrounded by a sort of magnetic whirl. A great part of the energy of the so-called electric current in the wire consists in these external magnetic whirls. To set up requires an expenditure of energy, and to maintain them requires also a constant expenditure of energy.

Fig. 5.—Magnetic Field of Bar-magnet.

It is these magnetic whirls which act on magnets, and cause them to set as galvanometer needles do, at right angles to the conducting wire.

Now, Faraday's principle is nothing more nor less than this:—That by moving a wire near a magnet, across a space in which there are magnetic lines, the motion of the wire, as it cuts across those magnetic lines, sets up magnetic whirls round the moving wire, or, in other language, generates a so-called current of electricity in that wire. Poking a magnet-pole into a loop or circuit of wire also necessarily generates a momentary current in the

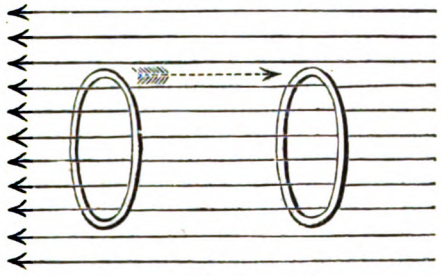

Fig. 6.

Circuit moved without cutting Lines of Force of Uniform Magnetic Field.

wire loop, because it momentarily sets up magnetic whirls. In Faraday's language, this action increases the number of magnetic lines of force intercepted by the circuit.

It is, however, necessary that the moving conductor should, in its motion, so cut the lines of force as to alter the number of lines of force that pass through the circuit of which the moving conductor forms part. If a conducting circuit—a wire ring or single coil, for example—be moved along in a uniform magnetic field, as indicated in Fig. 6, so that only the same lines of force pass through it, no current will be generated. Or, if again, as

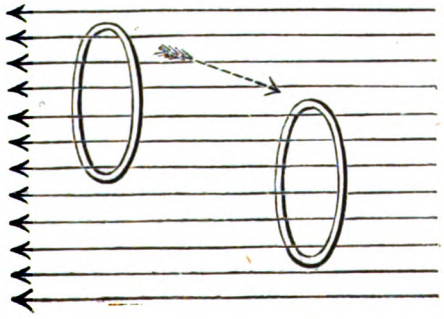

Fig. 7.—Circuit moved without cutting any more Lines of Force.

in Fig. 7, the coil be moved, by a motion of translation, to another part of the uniform part of the uniform field, as many lines of force will be left behind as are gained in advancing from its first to second position, and there will be no current generated in the coil. If the coil be merely rotated on itself round a central axis, like the rim of a fly-wheel, it will not cut any more lines of force than before, and this motion will generate no current. But if, as in figure, the coil be tilted in its motion across the uniform field, or rotated round any axis in its own plane, then the number of lines of force that traverse it will be altered, and currents will be generated. These currents will flow round the ring-coil in the positive* sense (as viewed from the point toward which the lines of force run), if the effect of the movement is to diminish the number of lines of force that cross the coil; they will flow round in the opposite sense if the effect of the movement is to increase the number of intercepted lines of force.

If the field of force be not a uniform one, then the effect of taking the coil, by a simple motion of translation, from a place where the lines of force are dense to a place where they are less dense, as from position 1 to position 2 in Fig. 9 will be to generate currents. Or, if the motion be to a place where the lines of force run in the reverse direction, the effect will be the same, but even more powerful.

We may now summarise the points under consideration, and some of their immediate consequences, in the following manner:—

(1.) A part, at least, of the energy of an electric current exists

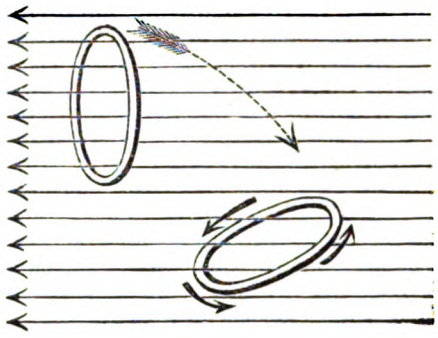

Fig. 8.—Circuit moved so as to alter number of Lines of Force through it.

in the form of magnetic whirls in the space surrounding the conductor.

(2.) Currents can be generated in conductors by setting up magnetic whirls round them.

(3.) We can set up magnetic whirls in conductors by moving magnets near them, or moving them near magnets.

(4.) To set up and maintain such magnetic whirls uses up a continuous expenditure of energy, or, in other words, consumes power.

(5.) To induce currents in a conductor there must be relative motion between conductor and magnet of such a kind as to alter the number of lines of force embraced in the circuit.

(6.) Increase in the number of lines of force embraced by the ciruit produces a current in the opposite sense to decrease.

(7.) Approach induces an electromotive force in the opposite direction to that induced by recession.

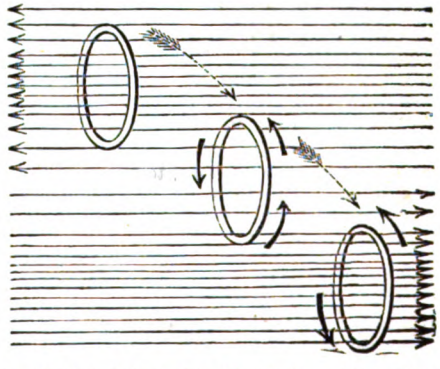

Fig. 9.—Motion of Circuit in Non-uniform Magnetic Field.

(8.) The more powerful the magnet pole or magnetic field the stronger will be the current generated (other things being equal).

(9.) The more rapid the motion the stronger will be the currents.

(10.) The greater the length of the moving conductor thus employed in cutting lines of force (*i.e.*, the longer the bars, or the more numerous the turns of the coil), the stronger will be the currents generated.

(11.) The shorter the length of those parts of the conductor not so employed, the stronger will be the current.

(12.) Approach being a finite process, the method of approach and recession (of a coil towards and from a magnet pole) must necessarily yield currents alternating in direction.

(13.) By using a suitable commutator all the currents, direct

* The positive sense of motion round a circle is that opposite to the sense in which the hands of a clock go round.

Digitized by Google

or inverse, produced during recession or approach, can be turned into the same direction in the wire that goes to supply currents to the external circuits, thereby yielding an almost uniform current.

(14.) In a circuit where the flow of currents is steady* it makes no difference what kind of magnets are used to procure the requisite magnetic field, whether permanent steel magnets or electro-magnets, self-excited or otherwise.

(15). Hence the current of the generator may be itself utilised to excite the magnetism of the field-magnets, by being caused, wholly or partially, to flow round the field-magnet coils.

A very large number of dynamo-electric machines have been constructed upon the foregoing principles. The variety is, indeed, so great that classification is not altogether easy. Some have attempted to classify dynamos according to certain constructional points, such as whether the machine did or did not contain iron in its moving parts (which is a mere accident of manufacture, since almost all dynamos will work either with or without iron in their armatures, though not equally well); or whether the currents generated were direct and continuous, or alternating (which is, in many cases, a mere question of arrangement of parts of the commutator or collectors); or what was the form of the rotating armature (which is, again, a matter of choice in construction, rather than of fundamental principle). The classification which I shall adopt is one which I have found more satisfactory and fundamental than any other. I distinguish three genera or main classes of dynamos.

Class I.—Dynamos in which there is rotation of a coil or coils in a uniform† field of force, such rotation being effected (as in the manner indicated in Fig. 12) round an axis in the plane of the coil, or one parallel to such an axis.

EXAMPLES.—Gramme, Siemens (Alteneck), Edison, Lontin, Bürgin, Fein, Schückert, Jürgensen (Thomson's mousemill dynamo) [Brush].

Class II.—Dynamos in which there is translation‡ of coils to different parts of a complex field of varying strength or of opposite sign. Most, but by no means all, of the machines of this class furnish alternate currents.

EXAMPLES.—Pixii, Clarke, Niaudet, Wallace-Farmer, Wilde (alternate), Siemens (alternate), Hopkinson and Muirhead, Thomson (alternate), Gordon (alternate), Siemens-Alteneck (disc dynamo), Edison (disc dynamo), De Meritens.

Class III.—Dynamos having a conductor rotating so as to produce a continuous increase in the number of lines of force cut, by the device of sliding one part of the conductor on or round the magnet or on some other part of the circuit.

EXAMPLES.—Faraday's Disc machine, Siemens's ("Unipolar" Dynamo), Voice's Dynamo.

One machine, and one only, am I aware of, which does not fall exactly within any of these classes,§ and that is the extraordinary tentative dynamo of Edison, in which the coils are waved to and fro at the ends of a gigantic tuning fork, instead of being rotated on a spindle.

Suppose, then, it were determined to construct a dynamo upon any one of these plans—say the first—a very slight aquaintance with Faraday's principle and its corollaries would suggest that, to obtain powerful electric currents, the machine must be constructed upon the following guiding lines:—

(*a.*) The field-magnets should be as strong as possible, and their poles as near together as possible.

(*b.*) The armature should have the greatest possible length of wire upon its coils.

(*c.*) The wire of the armature coils should be as thick as possible, so as to offer little resistance.

(*d.*) A very powerful steam engine should be used to turn the armature, because,

(*e.*) The speed of rotation should be as great as possible.

Unfortunately, it is impossible to realise all these conditions at once, as they are incompatible with one another; and, moreover, there are a great many additional conditions to be observed in the construction of a successful dynamo. We will deal with the various matters in order, beginning with the speed of the machine.

Relation of Speed to Power.

Theory shows that, if the intensity of the magnetic field be constant, the electromotive force should be proportional to the speed of the machine. Numerous experiments, by many different workers, have shown that this is true, within certain limits, for those machines in which the field magnets are independent of the main circuit, that is to say, for magneto and separately-excited dynamos. It is not, however, quite exact, unless the resistance of the circuit be increased proportionately to the speed, because the current in the coils itself reacts on the magnetic field, and alters the distribution of the lines of force. The consequence of this reaction is that, firstly, the position of the "diameter of commutation" is altered; and, secondly, the effective number of lines of force is reduced. So that, with a constant resistance in circuit, the electromotive force, and, therefore, the current are slightly less at high speeds than the proportion of the velocities would lead one to expect. Since the product of current into electromotive force gives a number proportional to the electric work of the machine, it follows that, for "independently excited" machines, the electric work done in given time is nearly proportional to the square of the speeds, and the work drawn from the steam engine will be similarly proportional to the square of the speed.

In self-exciting machines, whether "series" or "shunt" in their arrangements, a wholly different law obtains. If the iron of the field-magnets be not magnetised near to saturation, then, since the increase of current consequent on increase of speed produces a nearly proportional increase in the strength of the magnetic field, this increase will react on the electromotive force, and cause it to be proportional more nearly to the square of the velocity, which again will cause the current to increase in like proportion. But since the magnetisation of the iron is, even when far from saturation point, not exactly proportional to the magnetising force, but something less, it is in practice found that the electric work of the machine is not proportional to the fourth power of the speed, is not even proportional to the third power of the speed, but to something slightly less than the latter.

As mechanical considerations forbid too high a velocity in the moving parts, it is clear that, if there be a limiting speed at which it is safe to run any given armature, the greatest amount of work will be done at that speed by using the most powerful magnets possible, namely, electro-magnets rather than magnets of steel.

Marcel Deprez has shown* that it is convenient to study the action of dynamos, by constructing a curve which he calls a "characteristic," showing, for any given speed, the relation between electromotive force and strength of current generated in a circuit of given resistance. Amongst other conclusions, M. Deprez has found that for every dynamo there is a certain speed, which we may call the "critical speed," at which, no matter what the current is which circulates in the coils of the field magnets, the electromotive force is proportional to the strength of that current; and he bases upon the discovery of this critical speed two methods of utmost importance in practice, for obtaining, automatically, either a constant electromotive force or a constant current at will, in a circuit in which the resistances are varied to any degree.

In all these combinations, however, everything depends upon the condition that the driving speed shall be uniform. For all the best kind of electric work, a gas engine is wholly out of the question as a source of power, because of its extreme inequalities in speed. Even with the best steam engines, a specially sensitive valve is required; and, probably, such valves will, in the future, be operated electrically by self-acting electro-magnet gearing. In any case, where the driving is at all liable to be uneven, the obvious and simple precaution should be taken of placing a heavy fly wheel on the axis of the dynamo. It is, indeed, singular that this is not more generally done.

(TO BE CONTINUED.)

---

* For currents that are not steady, there are other considerations to be taken into account, as will be shown hereafter.

† Or approximately uniform. A Gramme ring, or a Siemens drum armature, will work in a by no means uniform field, but is adapted to work in a field in which the lines of force run uniformly from one side to the other. But in such a field, a multipolar armature of many coils, such as that of Wilde, or such as is used in the Gramme alternate current, or in the Siemens alternate current machine, is useless and out of place. Indeed, the classification almost amounts to saying that in machines of Class I. there is one field of force, while in machines of Class II. there are many fields of force, or the whole field of force is complex.

‡ The motion by which the individual coils are carried round on such armatures as those of Niaudet, Wallace-Farmer, Siemens (alternate), &c., is, of course, not a pure translation. It may be regarded, however, as a combination of a motion of translation of the coil round the circumference of a circle, with a rotation of the coil round its own axis, which, as we have seen above, has *no* electrical effect. It is, of course, the translation of the coil to different parts of the field which is the effective motion.

§ There are a few dynamos, including the Elphinstone-Vincent, and the four-pole Gülcher, which, though really belonging to the first class, are not named above, because they are, in reality, compound machines. The Gülcher, with its double field magnets and four collecting-brushes, is really a double machine, though it has but one rotating ring. The same is the case with an octagonal-pattern Gramme, which has four brushes. The Elphinstone-Vincent machine, a remarkable one in many respects, is a triple machine, having six brushes, and may, indeed, be used as three machines, to feed three separate circuits.

* *Comptes Rendus*, 1881, and elsewhere. For an excellent summary of the work of M. Deprez, see *La Lumière Electrique*, February 18, 1882.

DETECTION OF METALLIC MASSES IN THE HUMAN BODY.*

BY ALEXANDER GRAHAM BELL.

(CONTINUED FROM PAGE 167.)

Mr. Marean, of Washington, kindly lent me a number of condensers used by the Western Union Telegraph Company, and we found, upon connecting them with the coils E F, as shown in Fig. 17, and, holding a leaden bullet near the coils, that each condenser reinforced a high upper-partial of different pitch. We arranged the condensers so that they could be successively introduced into the circuit with great rapidity. The effect was very curious, and sounded somewhat like a Scotch air played upon the bagpipes. The low hum of the fundamental could be heard continuously like the drone of the bagpipe, while the higher tone changed its pitch with each change of condenser.

The pitch of the high tone reinforced seemed to depend upon the electrostatic capacity of the condenser employed, but the exact relation between the two has not been ascertained. In Experiments 5, 6, 7, 8, and the subsequent experiments described above, the battery employed consisted of six pairs of carbon and zinc plates of large area placed in a solution of bichromate of potash containing sulphuric acid.

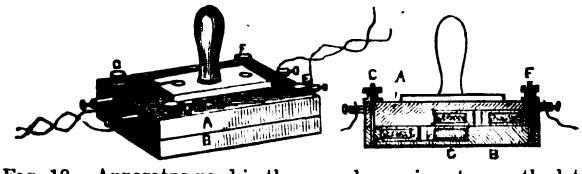

FIG. 18.—Apparatus used in the second experiment upon the late President Garfield, August 1, 1881.

The effects noted above were not produced satisfactorily when the battery was much run down, nor were they obtained with a Leclanché battery which had been set up for some time, but which appeared to be in good condition.

It is evidently necessary in order to produce this characteristic high tone to use a battery possessing considerable electromotive force and slight internal resistance.

Our experiments had reached this stage when, on Saturday, the 30th of July, 1881, I was requested to make another trial upon the person of the President at the evening dressing of the wound.

At this time, however, we had no exploring instruments completed excepting one or or two like that shown in Fig. 11; for it will be understood that the promising results noted above had been obtained from coils that were simply placed upon a table and adjusted by hand.

We immediately proceeded to the executive mansion with the apparatus shown in Fig. 13, prepared to make a trial, if it was deemed advisable; but upon learning of the results of our later experiments the surgeons resolved to postpone any further trial until we could arrange the coils (Fig. 17) in a portable form.

By forced exertions the coils were arranged that same night in a wooden case, as shown in Fig. 18. This case consisted essentially of two oblong

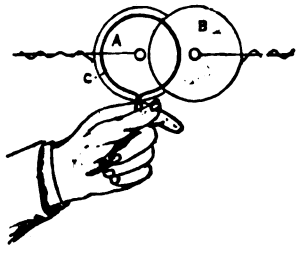

FIG. 19.

blocks A B. A shallow circular recess was turned out in each block for the reception of one of the coils, and the two blocks were held together by four pins of ebonite, C, D, E, F, which passed up through slots in the upper block and were secured by ebonite thumb-screws.

When the instrument was completed I found to my great distress that a balance could not be obtained by any adjustment of the apparatus. There was a position of minimum sound, and the telephone responded to a bullet presented to the central part G of the instrument; but the hearing distance did not exceed 3 or 4 cm., whereas we had obtained with the same coils before the construction of the wooden case a perfact balance and a hearing distance of 13 cm.

After numerous unsuccessful experiments had been made to ascertain the cause of the difficulty it occurred to me that if two adjoining convolutions in one of the coils made contact at any point a circuit of low resistance would be formed (a single ring of wire, in fact) in which the induced currents might circulate without reaching the telephone connected with the apparatus. I had previously measured the resistance of the coils without discovering any defect, but when I considered the large number of convolutions in each coil it seemed possible that a defect of this kind might exist which could not be discovered by a Wheatstone bridge except by very delicate and accurate observations. To test whether a short-circuited convolution would produce effects analogous to those observed, a piece of copper wire was bent into an annular form, and the ends connected together. On bringing this metallic ring near a pair of coils (A, B, Fig. 19) properly adjusted to silence the balance was loudly disturbed. The copper ring (C) was held as shown in Fig. 19, and the balance could not then be restored by any adjustment of the coils. A position of minimum sound was all that could be obtained, and the hearing distance was enormously reduced. This was *prima facie* evidence of the nature of the defect.

The coils (Fig. 18) were then removed from their case, but a cursory examination revealed no defect. Upon trial, however (being arranged, as formerly, in Fig. 17), a balance could not be obtained, and the hearing distance was only about four cm. The defect was thus definitely located in the coils themselves.

Upon close examination it was noticed that the outside convolutions of the primary coil were slightly frayed at one part, but it appeared hardly possible that so great a defect could be due to so apparently slight a cause. However, to test the matter, I removed the outside layer of wires and then tested the coils again.

Result: The defect had vanished—a perfect balance was obtained, and the hearing distance was again 13 cm.*

The coils were then replaced in their case and the completed instrument tested. The lower wooden block B (Fig. 18) was adjusted by hand as nearly as possible to the position of silence, and then the thumb-screws C, D, E, F were tightened.

The balance now obtained was not quite perfect, but by striking the lower block B a few smart blows with a wooden mallet we were able to reduce the arrangement to complete silence.

The instrument was then in such a sensitive condition that it could scarcely be moved without affecting the balance. Upon gently swaying it backwards and forwards a pulsation of sound was heard at every swing.

When the motion was carefully made, so that it was always in the same plane, no pulsations were observed. They only occurred when the inclination of the coils was changed.

This defect was found to be due to the bulging of the thin portion G of the wooden case (Fig. 18) under the weight of the enclosed coil, and the simple pressure of a finger on this portion of the case disturbed the balance. The movement of the lower coil when the instrument was swayed about must have been inconceivably small, but on account of the extreme sensitiveness of the arrangement it produced a perceptible effect upon the balauce.

The pulsating sound did not seem to interfere with the detection of a bullet held in the clenched hand, nor did it seem to affect the hearing distance. I, therefore, despatched a messenger to the Executive Mansion (Sunday morning, July 31st), with a note for Dr. Bliss, to let him know that the instrument was in a condition to be used, should any necessity arise for an immediate experimect. At the same time I informed him that the apparatus in its present form was very crudely constructed, and that I hoped to improve it very greatly in the course of a few days. On Sunday afternoon (July 31st) we sent to the Soldiers' Home for John M'Gill, upon whom we had experimented the previous day without results (using the apparatus shown in Fig. 11).

Upon trying the new instrument (Fig. 18) we had no difficulty in finding a sonorous spot in his back, at the place where the bullet was always supposed to be.

This result was at once communicated to Dr. Bliss, and in reply we were requested to make the experiment upon the person of the President next morning.

On Monday morning (August 1st, 1881) we accordingly removed our apparatus to the Executive Mansion.

The late President Garfield.

During the former experiment (July 26) a sudden sonorous effect had been observed upon passing a point near the spot where the surgeons suspected the bullet to be lodged, but I had been unable to verify this by a second observation, although the exploring instrment (A B, Fig. 13) was repeatedly passed over the same place. The sound had been so loud and well marked that I believed at the time it must have been caused by a sudden irregularity in the vibration of the reed of the rheotome used to interrupt the primary circuit, for the arrangement (as explained above), was not perfectly balanced, and any irregularity of this kind would, under these circumstances, have affected the telephone. At the same time the coincidence was remarkable that the exploring instrument should have been at that very time so near the suspected seat of the ball, and this led to the thought that perhaps after all the bullet had been the cause of the sound. I felt confident that the new instrument (Fig. 18) would at once decide the question, for the extreme hearing distance of the former apparatus (Fig. 13) was only 6cm., and the apparatus shown in Fig. 18 was so superior in this respect that if the sound had really been due to the bullet we should obtain with the new instrument distinct and well-marked effects. When the new explorer (Fig. 18) was passed over the suspected

* A Paper read before the American Association for the Advancement of Science at the Montreal Meeting, August, 1882.

* These experiments have revealed the cause of the extreme difficulty always experienced in obtaining a perfect balance with coils of fine wire. I have recently used an induction balance to test the condition of the helices that were employed in these researches, and have discovered that in a large percentage of cases the insulation was defective. It is possible that some of the results described in this paper (especially of the earlier experiments) may have been vitiated by errors due to defects in the coils that were not suspected at the time. A defect of insulation that is quite immaterial for ordinary purposes may be absolutely fatal to the success of an induction balance. Indeed, so much care is required in this respect that it is extremely difficult to obtain coils that are perfectly suitable for an apparatus intended to search out a bullet imbedded in the body. I now make it a rule to test every helix used in induction balance experiments by bringing it up to a system of balanced coils like that shown in Fig. 17.

1. If the helix is perfect the balance is not disturbed until the terminals of the coil are connected.

2. If there is a break in any of the convolutions the balance is not disturbed, even when the terminals are connected.

3. If a convolution is short-circuited the balance is disturbed, even though the terminals are not connected, and the sound produced is the fundamental of the rheotome employed to interrupt the primary circuit.

4. If the insulation is defective the balance is disturbed, although the terminals are not connected, and a peculiar spluttering effect is noticed like that produced by a series of sparks.

I propose to apply this method practically as a means of testing the condition of the helices used in the construction of induction coils and those employed in the manufacture of telephones.

Digitized by Google

spot nothing was heard excepting a slight pulsating sound as the instrument was moved to and fro. This was evidence to me that the former sound had been of accidental origin, whether the bullet was there or not. With the view of eliminating any error of observation caused by pulsations due simply to the movement of the instrument, I lifted the latter (without changing the inclination of the coils) to a height of about 50 centimetres above the body of the President, and moved it to and fro in as nearly as possible the same way I had done at the lower elevation.

I presumed that if the pulsations heard were due simply to the movement of the instrument, they should occur with equal strength at the two elevations; but if any portion of the sonorous effect was due to the influence of the bullet, the pulsations at the two elevations would be different in intensity. I was struck by the fact that, although the sonorous pulsations were very feeble, they were sensibly louder when the instrument was close to the surface of the body than when it was raised. Continuing the exploration, I found a considerable area over which similar effects were noticed, but upon carrying the instrument towards the back of the President, the difference between the pulsations produced at the two elevations grew less and less, and finally could not be distinguished.

The difference in the loudness of the sound at the two elevations was so slight that it probably would not have been noticed by an ear unaccustomed to listen to feeble effects, and I feared that the general expectation that the bullet would be found in that part of the body might have led me to imagine a difference that did not exist. For the purpose of eliminating as far as possible any personal error, I requested Mr. Sumner Tainter (who was the only other person present whose ear had been sufficiently trained to be reliable in such an emergency) to repeat the experiments and let me know the result. Upon our return to my laboratory we compared notes, and I found that his observation tallied with mine. He declared he could not obtain a distinctly localised effect, but stated that he had observed a reinforcement of the pulsation over an area of at least two inches in the neighbourhood of the spot to which his attention had primarily been directed, and that he was convinced that the bullet was within that area.

It appeared reasonably certain that the area of feeble sound was due to some external cause, and was not simply an effect of expectancy. In the absence of any other apparent cause for the phenomenon I was forced to agree in the conclusion that it was due to the presence of the bullet, and I so stated in my report to the surgeons. I was by no means satisfied, however, with the results obtained, for no such effects had been observed before in our experiments with bullets. I tried to reproduce the effects by moving the instrument (Fig. 18) at different distances over a bullet, but in every case where an effect was produced the sound was quite sharply localised. I thought that perhaps the body of the patient might have affected the result, and so experimented upon a bullet buried in a piece of meat, but no difference of effect was noted. This led me to fear that the extensive area of feeble sound might have been due to some extensive area of metal that was unsuspected at the time, and I proceeded to the Executive Mansion next morning (August 2) to ascertain from the surgeons whether they were perfectly sure that all metal had been removed from the neighbourhood of the bed. It was then recollected that underneath the horsehair mattress on which the President lay was another mattress composed of steel wires.

Upon obtaining a duplicate, the mattress was found to consist of a sort of net of woven steel wires, with large meshes. The extent of the sonorous area having been so small, as compared with the area of the bed, it seemed reasonable to conclude that the steel mattress had produced no detrimental effect.* I was unable to continue experiments with the steel mattress, as just at this time I was obliged to leave Washington on account of illness in my family. Although I was unable for a long time afterwards to carry on personally induction balance experiments, the investigations were ably continued under my direction by Mr. Thomas Gleason, in the establishment of Mr. Charles Williams, jun., in Boston.

(TO BE CONTINUED.)

THE WESTERN AND BRAZILIAN TELEGRAPH COMPANY (LIMITED).

Report of the directors, to be presented at the tenth ordinary general meeting of the Company on January 11, 1883:—The directors submit their report and the accounts of the Company for the year ended September 30, 1882. During the year communication has been opened with Maldonado and Ceara, and it has been found necessary, owing to the great length of the Company's system (3,700 miles) and the consequent expense and delay in making repairs, to contract for the purchase of a second steamer. The total earnings amount to £115,169 16s. 11d., a decrease of £1,221 8s. 7d. compared with last year. In addition to which £936 8s. 5d. has been recovered from the underwriters in *re* the Quintero case, and £2,938 18s. 1d. for interest on deposits, the total gross receipts being £119,095 3s. 5d., against £118,882 7s. 2d. The working expenses for the year amount to £61,919 3s. 8d., as against £70,461 10s. 3d, a decrease of £8,542 6s. 7d. The maintenance for the year amounts to £31,728 10s. 2d., as against £41,807 9s. 3d. After paying the debenture interest the balance remaining to the credit of the net revenue account is £30,175 19s. 9d., against £16,559 1s. 6d. for 1880 1881. Since the last report a further sum of £6,693 8s. 6d. has been recovered on account of the compromise of the suit previously mentioned, finally closing this litigation. The total amount recovered the directors have, under the advice of counsel, placed to the credit of renewal account. The directors are of opinion that the time has now arrived to deal with the readjustment of the capital account of the Company, and have submitted a case to Sir Henry James, Her Majesty's Attorney-General, and Mr. Horace Davey, Q.C., who have advised that the capital lost should be written off, and that until this has been done any surplus revenue of the Company cannot properly be appropriated for dividend purposes. In their last report the directors stated that it was no longer advisable to retain the Central American Company's Securities upon the books of this Company as an asset. The shareholders are aware that the matter has been the subject of consideration for some years past, and that the auditor has repeatedly suggested that the amounts represented by these securities should be written off; this suggestion the directors recommend for the adoption of the shareholders. In addition to the losses caused by the Central Company, it is thought expedient to reduce the capital account by an amount which it has been found necessary to expend in order to place the cables in a more efficient condition, and by certain claims for depreciation, ship, instruments, &c., which will increase the amount to be written off to £5 per share, or £349,550, which is thus made up:—Central Company, £284,521 9s. 4d.; outlay for renewal, depreciation of ship, instruments, &c., £65,028 10s. 8d.; total, £349,550. It has been suggested by a large and influential body of the proprietors that the shareholders should have the option of dividing their shares into two classes of equal nominal value:—1. Preferred Ordinary, carrying (as against the Deferred Ordinary shares) a preferential dividend of 5 per cent., cumulative. 2. Deferred Ordinary, which shall be entitled to the surplus earnings declared applicable for dividend after the dividend payable on the Preferred Ordinary shares. The annexed special resolutions for the reduction of the capital, and otherwise, will be submitted to the shareholders at the extraordinary meeting to be held after the ordinary annual meeting. Including the amount brought forward from last year, the balance to the credit of the net revenue account is £48,250 11s. 11d., out of which amount the Board propose to place £12,000 to the renewal fund, and when the necessary legal formalities for reduction of the capital have been complied with, will recommend the division among the shareholders of 3 per cent. on the reduced capital, or £31,459 10s., free of income-tax, carrying forward the balance to next account. This will give, if the proposed division of shares is carried out, a dividend of £5 per cent. to the Preferred Ordinary, and £1 per cent. to the Deferred Ordinary shares. The retiring directors are Messrs. Wood and Andrews, who offer themselves for re-election. The auditor, Mr. Weise, retires, and is eligible for re-election.

* The death of President Garfield, and the subsequent *post-mortem* examination, however, proved that the bullet was at too great a distance from the surface to have affected our apparatus.

SLIP

DIVIDEND.—The directors of the German Union Telegraph Company announce an interim dividend of 5s. 9d. per share.

RAILWAY AND ELECTRIC APPLIANCES COMPANY.—A special meeting of this company has been called for the 24th inst.

BRAZILIAN SUBMARINE TELEGRAPH COMPANY.—The traffic receipts of this company for the week ended 5th inst. amounted to £3,356.

THE INVENTORS' INSTITUTE.—On Thursday last Mr. T. Morgan was to read a paper on Recent Electrical Patents before the Inventors' Institute.

RESIGNATION.—Mr. A. L. Lineff has resigned the office of electrical engineer to the London and Provincial Electric Lighting and Power Generating Company.

INDIAN TELEGRAPH DEPARTMENT.—A Reuter's telegram from Calcutta, dated Jan. 5, says that the Indian Postal and Telegraph Departments are not to be amalgamated.

MESSRS. FERRANTI, THOMSON, AND INCE.—We are informed that Sir Charles Laurence Young, Bart., has joined the board of directors of Ferranti, Thomson, and Ince (Limited).

EASTERN TELEGRAPH COMPANY.—The traffic receipts of this company for the month of December, 1882, amounted to £49,610, and to £49,844 in the corresponding period of 1881.

ELECTRIC LIGHTING AT THE MINT.—The Royal Mint, which has just been entirely reconstructed, will be lighted by electric light, and telephones will be largely used throughout the building.

WEST INDIA AND PANAMA TELEGRAPH COMPANY.—The estimated traffic receipts of this company for the half month ended Dec. 31 are £2,080, as compared with £2,405 in the corresponding period of 1881.

EASTERN EXTENSION TELEGRAPH COMPANY.—The traffic receipts of this company for the month of December, 1882, amounted to £31,617, and to £31,319 for the corresponding period of 1881, being an increase of £298.

LONDON PLATINO TELEGRAPH COMPANY.—The revenue of this company for the month of October is estimated at £2,112 (Western Brazilian portion £1,546, land lines £566), as against £1,856 for the corresponding period of 1881.

ELECTRIC LIGHTING AT LIVERPOOL DOCKS.—The Mersey Docks and Harbour Board have made an alteration in one of their bye-laws, whereby work will be allowed to be carried on on board ships in graving docks by the use of electric lights or gas.

SOCIETY OF TELEGRAPH ENGINEERS AND OF ELECTRICIANS.—At the meeting of the society, to be held on Thursday. the 18th inst., at 8 p.m., Mr. Willoughby Smith will deliver his inaugural address, as president, for the ensuing year.

ELECTRICAL EXHIBITION AT VIENNA.—We have received official notice that this exhibition will be opened in Vienna on the 1st August next, and will remain open until the following 31st October. The office of the Organising Committee is at I Wallfischgasse 9A, Vienna.

ELECTRIC LIGHT IN BERLIN.—The Berlin correspondent of a daily paper says that during the festivities at the Old Castle (belonging to the Imperial Family) this season all the rooms are to be illuminated with the electric light. The work of preparation has already begun.

THE CHARING CROSS ELECTRIC RAILWAY.—The inhabitants of part of the district through which it is proposed that this railway and its extensions shall pass have resolved to oppose the scheme. They have called on the Lord Mayor to summon a meeting of citizens at an early date to consider the matter.

DIRECT SPANISH TELEGRAPH COMPANY.—The estimated traffic receipts of this company for the month of December, 1882, were £1,346, against £1,458 in the corresponding period of last year. In December, 1881, the Bilbao cable was interrupted 15 days; in December, 1882, the Barcelona cable was interrupted 23 days.

ELECTRIC LIGHTING IN DUBLIN.—At a meeting of the Lighting Committee of the Dublin Corporation, held last week, the question of electric lighting was discussed, and it was unanimously resolved to engage the services of Mr. Angelo Fahie, C.E., of Dublin, as consulting electrician to advise the committee on the subject.

THE ELECTRIC LIGHTING ACT, 1882.—The Board of Trade have made the following rule, in pursuance of Section 5 of the above Act:—"The time provided for by Rules 4 and 11 of the rules made by the Board of Trade shall be the 1st day of February, instead of two months from the date of the newspaper containing the first advertisement of the application."

THE ROYAL SOCIETY.—The following paper by Lord Rayleigh and Mrs. Sidgwick was to have been read before this society on Thursday, viz.:—"Experiments, by the Method of Lorentz, for the Further Determination of the Absolute Value of the British Association Unit of Resistance; with an Appendix on the Determination of the Pitch of a Standard Tuning Fork."

APPOINTMENT.—Mr. George Carrick Steet, second medical officer to the General Post Office, has been promoted to be chief medical officer, in the room of the late Dr. Waller Lewis, and Mr. A. H. Wilson, the present assistant, succeeds Mr. Steet as second medical officer. We also understand that it is the intention to appoint a lady to take the medical superintendence of the female branches of the establishment.

ELECTRIC AND GAS LIGHTING AT SHEFFIELD.—At a meeting of the Electric Lighting Committee of the Sheffield Town Council, held last week, a report was read from Mr. Conrad Cooke, electrical engineer retained by the corporation to advise as to applying to the Board of Trade for a provisional order under the Electric Lighting Act, in which he recommended that the streets of the town should not be lighted by electricity but by gas.

BRITISH GUIANA.—The *Colonies and India* says that, according to the latest mail advices, it was announced in this colony that the Federal Council of the Leeward Islands had voted an increase of £1,000 per annum to the subsidy of the West India and Panama Telegraph Company. The local press, commenting upon this, considered that if similar concessions were made by the other West Indian colonies the Telegraph Company might yet get out of its present difficulties.

PURCHASE OF TELEGRAPH WORKS.—The directors of the Railway and Electric Appliances Company have concluded a provisional contract with Messrs. Latimer Clark, Muirhead, and Co., electric telegraph engineers and manufacturers, of Millwall and Westminster, for the purchase of their extensive works and business, as from the 1st January inst. The company secure the services of both Mr. Latimer Clark and Mr. Muirhead, the former as director and the latter as manager of this branch of the company's business.

ELECTRIC LIGHTING FOR CANTERBURY.—The Town Council of Canterbury have determined to endeavour to secure the

Digitized by Google

insertion of clauses in the provisional order applied for by the South Eastern (Brush) Electric Light Company, providing that reasonable notice should be given to every consumer whenever the supply is to be taken off during the daytime, to retain full control over the breaking up of the streets, and that the works should be placed in a suitable situation, and at a place prepared by the city surveyor.

Lectures on Electricity.—A course of ten lectures on electricity will be given, at the instance of the Society for the Extension of University Teaching, by T. W. Waghorn, Esq., R.N., in St. Jude's School Room, Commercial-street, Whitechapel, E., on Tuesday, the 16th, and the nine following Tuesdays, at 8:15 p.m. The lectures will be illustrated by experiments and intelligible to beginners. Further information may be obtained from the hon. secs., F. Rogers, 62, Nicholas-street, Mile End, E., and A. Milner, 54, Claverton-street, S.W. The introductory lecture, on the 16th inst., is free.

To be Wound Up.—At a meeting of the Dublin Electric Light Company on Thursday week it was decided that the company should be voluntarily wound up, and an endeavour made to sell the company's plant and connection as a going concern. The company was formed in June, 1881, with a capital of £150,000 in £10 shares, of which 4,070 shares were taken up. A sum of £4 per share was called up, making a total of £16,280 subscribed. Mr. Gardner, of Messrs. Gardner, Craig, and Co., was appointed liquidator, and a committee of five shareholders requested to superintend the winding-up proceedings.

The Bradford Chimney Accident.—In consequence of the fall of a large chimney on Thursday, the 28th December, at Bradford (Yorks.), extraordinary pressure was suddenly put on the postal telegraph office there, and lasted for several days. Up to the 4th instant about 100,000 words had been signalled. On the day of the catastrophe about 20,000 words were forwarded from eight to ten p.m., all of which were disposed of by 10:30, although no previous notice could be given of the work. Direct communication was established with all the principal towns in the United Kingdom, including Aberdeen, Dundee, Edinburgh, Glasgow, Newcastle, Liverpool, Manchester, Bristol, Birmingham, Sheffield, Nottingham, London, &c. Considerable credit is, we think, due to the Bradford telegraph staff for the efficient way in which they have met this sudden call on their energies.

Electric Lighting at Newcastle-on-Tyne.—The *Newcastle Chronicle* says:—"Yesterday evening (Jan. 9) the steamer "Augusta," Capt. Arp, of Kiel, was discharged at Messrs. Davidson's wharf, Close, by the light given by a couple of electric lights carried on board the vessel. The lights—which are driven by the engines of the steamer—are placed in sex-angular lamps of medium size, fixed on at each end of the centre hold, in which the grain cargo is carried. The lamps are stated to be a Hamburg invention, and the company to which the "Augusta" belongs have seventeen of their vessels now supplied with them. The lamps seen at the Close last night have been in use on board the steamer for about a month, and the crew state that whenever they have been utilised they have given the utmost satisfaction. The lights, which are placed about 20 feet above the deck, are only used for loading and discharging purposes, and are never employed as signal or night lights at sea."

Exhibition of Incandescent Lighting in India.—The *Times of India* says:—"On the evening of the 21st December a large party of ladies and gentlemen assembled by invitation at Bella Vista, Cumballa Hill, the residence of Major Strutt, the managing director of the Eastern Electric Light and Power Company, to witness an exhibition of electric lighting on the incandescent principle. The interior of the bungalow, together with its spacious verandahs and the grounds adjoining were lighted by means of some fifty or sixty lamps of the Lane-Fox pattern, each lamp averaging about 20 candle-power. The lamps were arranged in a variety of ways so as to show the extreme adaptability of the light to domestic uses, and the result was a success in every way. The current was provided by means of a number of accumulators which had been previously charged with electricity at the company's works at Mody Bay, and conveyed to Cumballa Hill by coolies. One of the greatest novelties of the exhibition was the illumination of a fountain in the compound, the visitors being enabled, by means of a clever arrangement of lamps placed under water, to see with perfect distinctness the gold fish swimming about in the water."

Electric Lighting for the City.—At a meeting of the Commissioners of Sewers, on Tuesday last, Mr. Stoneham presented a report from the special committee appointed to consider the question of the electric lighting of the City, which recommended that the commissioners should apply under the Electric Lighting Act for a special license to light a small area and permissive powers for a larger area.—Mr Pannell inquired how the committee proposed to set about lighting the small area?—Mr. Stoneham said it was suggested that they might contract with a company.—Mr. Pannell pointed out the difficulty of the commissioners delegating their powers to a company, and, as an amendment, moved that the report should be referred back, particularly as no facts were given in the report for the court agreeing with their conclusion.—Mr. J. S. Scott seconded the amendment, urging that if they were to relegate to a company their powers they would be absolutely in the hands of one company.—Mr. Alderman Staples, who originally opposed such a proposal, said that he had altered his opinion, and he thought that if they found the light successful over the small area they might very well extend it.—After remarks from Mr. Waller and Mr. Borr, the report was adopted.

Electrical Exhibition at the Royal Aquarium.—We understand that Mr. Musgrave Heaphy, C.E., has been appointed to report upon the fire risk of the above exhibition, and that he has already inspected the installations as far as they have progressed, and given detailed instructions as to the safeguards to be adopted. All the electric companies will be glad to learn that it has been placed in his hands, Mr. Heaphy being not only a practical electrician himself, and having had the superintendence of large installations, but he possesses great knowledge and experience on all matters connected with fire risk, particularly that of hazardous buildings, a combination of knowledge at present absolutely unique. The fair and impartial course Mr. Heaphy has pursued towards electric lighting, while never losing sight of the interests of the fire offices, has created great confidence in the minds of the electric companies whose work he has had to officially inspect. His rules and regulations are too well known to need any comment here, but it is not so generally known that the fire risk of electricity is a very old study of his, and that as long as six years back he was called upon to report to the Phœnix Fire Office upon the matter, that being probably the first official report ever made upon the subject.

Slaughtering by Electricity.—A correspondent of a daily paper writes:—"The suggestion for rapid killing of animals by means of electricity has been actually carried out. Some years ago Dr. Richardson made use of the large induc-

Digitized by Google

tion coil up in the Royal Polytechnic Institution for testing the question, and killed several sheep and other animals by the electric shock. The experiments led to results which were, to a certain degree, promising, and to a certain degree disappointing. The electric discharge always succeeded in striking the animals into instant insensibility, and in many instances the animals so stricken were positively killed; but in other instances, after the temporary production of all signs of death, there were indications of recovery, so that the death had to be completed by other means. It was found also that, when animals intended for human consumption as food were killed by the shock, some parts of the animal were marked by dark lines and spots, which to a considerable extent interfered with the sale of the carcases. Lastly, it was found that the dangers to the workmen attendant on the systematic introduction of the method into general use afforded an important reason for not recommending it. At the same time, the question remains *sub judice*, and the Council of the London Model Abattoir Society proposes to consider the electric with other painless methods of taking away the life of those members of the inferior creation which minister during their lives to our pleasures or our necessities."

The Yorkshire Brush Electric Light Company, Leeds.—This Company now appears to be securing a large amount of work, which, we understand, is fairly remunerative. As noticed in our issue of the 30th ult., they are lighting up the Theatre Royal, Dewsbury, and will continue to do so during the whole pantomime season under contract. As a direct result of their great success in the lighting of Dewsbury Theatre Royal, a similar contract has this week been signed for illuminating the Theatre Royal at Huddersfield, the Company using, as at Dewsbury, a patent headlight lamp for scenic effects during the "grand ballet" and other scenes. They have also received instructions to light up the underground markets of the Huddersfield Corporation, at Huddersfield, these markets being at present lighted throughout with gas; and, owing to intense heat, it has been decided to adopt the Brush system for illuminating the markets throughout. The Company are now busily engaged in fixing apparatus, &c., requisite for this work. On the 23rd inst., at the Town Hall, Huddersfield, Professor Allen, of Sheffield, will deliver a lecture on "The Philosophy of the Electric Light," when the large hall will be illuminated with Brush arc lamps, a system of switch arrangements being provided on the lecture table for demonstration purposes by the lecturer. Professor Rücker, of the Yorkshire College, is at present delivering a course of lectures on Electrical Science, at the Philosophical Hall, Leeds, and on Wednesday, the 31st inst., the Yorkshire Brush Electric Light Company will again illuminate the large hall by means of Brush arc and Lane-Fox incandescent lamps.

Electric Lighting in London.—The Mile End Old Town Vestry have adopted the report of their Special Committee on Electric Lighting, which was to the effect that "the knowledge of electric lighting is so slight that it is not advisable for the vestry to become undertakers under the Electric Lighting Act, and that the Board of Trade should refuse to sanction a provisional order for the next twelve months at least to enable proper consideration to be given to the matter." The Islington Vestry have, by a majority of fifty to eight, resolved to adopt the report of their special committee, as summed up in the following paragraph extracted therefrom, viz.:—"That in the existing state of electric lighting, and as far as the committee have been able to ascertain the probable costs of introducing the electric light into the parish, they are of opinion that it is undesirable that the vestry should become the undertakers." A committee of the Chelsea Vestry are considering the Metropolitan Brush Company's order for their district, and will report thereon soon. Messrs. Ferranti, Thomson, and Ince will not proceed with their order for this district, though they may take action in the matter towards the end of this year. The clerks of the St. George's-in-the-East and other vestries in the neighbourhood, such as Limehouse and Whitechapel, who are affected by the order of the Brush Metropolitan Company, are about to meet in order to take concerted action in the matter. They do not at present seem to be very favourably disposed towards electric lighting. The Camberwell Vestry, after a lengthy discussion, have resolved to oppose any application for a provisional order. As, however, the motion to apply for a license themselves was only negatived by 26 to 19 votes, it seems as if the prospects of electric lighting in Camberwell are not so very bad. The St. Olave's Board of Works have unanimously resolved not to apply to the Board of Trade for a license under the Electric Lighting Act. It was moved at a recent meeting to accept an offer made by Mr. Lane-Fox to light the district with incandescent lamps at a less cost than gas, but the question was adjourned for further consideration.

Electric Sparks and Electrostatic Actions.—The following is an abstract of a paper by M. Aug. Righi in the *Comptes Rendus*, published in a recent issue of the *Phil. Mag.*:—"Known experiments show that the electric discharge commences when the electric density on the electrodes has attained a sufficient value relatively to the dimensions of the balls, their quality, distance, &c. Supposing that the discharge is constituted by the emission of electrified particles, it will commence at that one of the two electrodes on which the density is the greater—from which we derive the explanation of many phenomena. If, then, at but little distance from the place where the spark is formed there are other electrified bodies, the particles will deviate from their path, moving away from the bodies which have charges of the same name as that of the electrode which repels them, and approaching the bodies charged with the contrary electricity. Now, the spark must pursue the path of the first particles repelled; for, by reason of the heat evolved, it offers less resistance. Therefore, the spark itself will deviate, as if it were a body charged with electricity of the same sign as that of the electrode on which the density previous to the discharge is the greater. The following is one of the ways in which I have verified this class of facts:—The two stems bearing the discharge-balls are arranged vertically one below the other, and at equal distance two parallel vertical discs are kept constantly charged, the one with positive, the other with negative electricity, by a Holtz machine with auxiliary combs, the exciters of which are sufficiently distant from one another for the sparks not to explode. It is readily observed that, when the two discs are not charged, the form of the spark produced between the two stems by the discharge of a condenser charged by another Holtz machine is nearly a straight line (if the distance between the balls is not too great); but if the discs are charged and if the two balls are not in all respects identical, the spark is curved, approaching the one or the other disc. The changes of shape are very remarkable when a liquid resistance such that the spark becomes yellow is inserted in the discharge-circuit. The spark then takes very curious forms, and at the same time it is observed to start from points of the electrodes situated laterally. Suppose, for example, that the two balls are identical in dimensions and

Digitized by Google

quality, but that one of them, the negative, communicates with the earth; the greater density is then on the positive ball, and it is there that the discharge will commence. The spark, in fact, is displaced and deformed as a positively electrified flexible body would be. The same effect is obtained if, both balls being insulated, the diameter of the negative is greater than that of the positive ball."

Accumulators.—We have received a copy of certain "instructions" which the Electrical Power Storage Company, of 4, Great Winchester-street-buildings, E.C., have drawn up for the information of those using their accumulators. We extract the following items, which refer to the Faure-Sellon-Volckmar accumulators:—"The cells comprising the accumulator are composed of a certain number of positive and negative electrodes, the different plates of the electrodes being joined together, thus forming one single element. The plates are immersed in a solution of sulphuric acid of 1,250 degrees specific gravity. In all the cells the positive pole is marked with red and the negative with black colour. The electromotive force of each cell, irrespective of size, is 2·15 volts, and remains practically constant up to the economical point of discharge. If the discharge is continued beyond this point one or more cells must be added to the circuit to maintain the E.M.F. Where the accumulator is properly used, as hereafter described, the effective return is 90 per cent. of the electrical energy stored. Great care must be taken that, before the dynamo machine is connected with the accumulator, the poles of the dynamo are well ascertained. This may be easily done by making a simple voltmeter with two plates of lead put into a glass of water with a few drops of sulphuric acid. The positive pole is that of which the lead becomes immediately peroxidised or black. This must be coupled to the positive or red pole of the accumulator. The cells must be coupled the positive to the adjoining negative and so on, the red and black poles being coupled the one to the other. The last cell of the accumulator must be coupled, the black pole to the negative pole of the dynamo. To bring the accumulator to its normal state of activity it is desirable to charge and discharge twice at least in order to get rid of the sulphate of lead which forms on the plates when the accumulator is allowed to remain dormant. This also applies to cases where the accumulator has not been used for some time. Special care must be taken to have the accumulators well insulated, as any moisture being permitted to remain between the cells occasions a considerable loss of E.M.F. on the whole battery. Before switching the accumulator on to the dynamo the latter should be going at its full rate of speed, otherwise its E.M.F. would be less than that of the accumulator, which in that case would overpower the dynamo and reverse the current. Care must be taken to keep the plates entirely submerged. To always maintain the same E.M.F., 25 per cent. of the electrical energy which the accumulator is capable of receiving must be allowed to remain, and 75 per cent. may be withdrawn. For example, an accumulator composed of one h.-p. cells should at first be charged with 400 amperes of current; then, when 300 have been withdrawn, 330 should be put in again. This permits a further 300 amperes to be taken out, still leaving 100 amperes in the accumulator. The same proportion applies to the various sizes. The rates of economical charge and discharge of the respective sizes are as follow:—One h.-p. cells charge 20—25, discharge 30—40 amperes; two h.-p. cells charge 40—50, discharge 60—75 amperes; five h.-p. cells charge 100—125, discharge 150—175 amperes."

Mr. Edison.—A correspondent recently communicated some account of Mr. Edison's doings in New York to *The Times*. Most of what he has to say has been anticipated in our columns. We may, however, make the following excerpt from his communication:—"At the Edison Machine Works, at Goerk-street, New York, the dynamos, large and small, are manufactured. Six dynamos of the largest size were awaiting shipment to London; four were being prepared for Milan, where a central station on the Edison system is being organised by Professor Colombo. The factory of Bergmann and Co. is exclusively devoted to the manufacture of switches, fittings, sockets, regulators, and other details of the complete Edison electric light system. Here also the application of electricity as a motive power and lighting agent was manifested in an impressive manner. Mr. Edward H. Johnson, whose name is well known in London, together with Mr Edison, is continually at work improving the minutæ of the system. I was shown a simple screw, the sole survivor of forty-two separate and discarded models which had failed to satisfy Mr. Edison's standard of efficiency. As an example of American manufacture and administative power, the following is an instance:—An order to light the Boston Bijou Theatre with 650 lights was completed within eleven days after receipt of the order. The theatre was wired, the boilers and engine were placed in position, the streets excavated, and the special regulating system necessary for subduing the lights on the various circuits on the stage or auditorium not only devised and manufactured in New York, but used in position. The writer was present at the opening of the theatre when Gilbert and Sullivan's "Iolanthe" was produced, and all the necessary scenic effects obtained by the use of the Edison light alone. The theatre was better lighted than the Savoy in London, and the regulation of the lamps seemed to be under more immediate control. [Without in the least wishing to detract from the work of the Edison Company, we may remind our readers that this is the mere *ipse dixit* of an anonymous writer.] The feasibility of accomplishing this work in so short a time arose greatly from the absence of such municipal and legislative restrictions as in England impede the progress of electric lighting in every direction. During past years Mr. Edison has suffered from injudicious, because premature, revelations of his inventions, and for some time, therefore, he has remained silent whenever pressed for information as to the progress of his inventions. Some months have elapsed since the Edison system was first shown to the English public at the Crystal Palace, and, as is well known, it is in operation at various places. Since then Mr. Edison has, however, not been idle. He has made remarkable discoveries, the effect of which is greatly to increase the efficiency and reduced the cost of the light. These discoveries include a considerable improvement in the dynamos and the invention of a more economical lamp of very high resistance. It is interesting to know that the development of the capacity of the machines does not involve the disuse of any of its parts. Nothing is made obsolete. A simple and inexpensive addition increases, to use popular language, the electrical out-turn, and by the use of the improved lamp more light is obtained from a given quantity of electricity than is now the case. Patents for these and other improvements have already been applied for, both in England and the States, and the English companies will shortly give a public demonstration of the new inventions. Mr. Edison's knowledge of the conditions of the electric light question in England is complete. To his mind the price of gas in England is the one factor in the problem which requires solution. It is this problem to which he has applied himself with so much success."

ELEMENTARY ELECTRICITY.

VI.

A number of Leyden jars whose coatings are connected together constitute a "Leyden battery," and serve for the accumulation of a large quantity of electricity at high potential, when they of course become the receptacle of a considerable amount of electric energy.

Suppose there are n jars, each of capacity C, and charged to potential V. The energy stored in each jar will be $\frac{1}{2}$ C V^2 ergs, and the whole energy of the battery will, therefore, be $\frac{1}{2}$ n C V^2 ergs. The charge of each jar will be C V units, and the whole amount of electricity communicated to the battery by the machine employed in charging it will be n C V units.

When it is required to charge a number of jars to a potential very much less than that which the electric machine employed is capable of producing, the "cascade" arrangement is sometimes adopted. For reasons which will presently appear, it is very seldom that this arrangement is of any real value, but as it is precisely similar to the arrangements of a voltaic battery or a number of "accumulators" in series, it is worthy of attention here.

To charge a Leyden battery in cascade, each jar, except the last, is placed upon a separate insulating support, and while the inner coating of the first jar is connected with the prime conductor of the electric machine, the outer coating is in communication with the inner coating of the second jar, the outer coating of the second is connected with the inner coating of the third, and so on, the outer coating of the last jar being put to earth. Suppose that there are six jars, and let them be called A, B, C, D, E, F. Suppose, further, that the opposite charges of the two coatings of each are numerically equal. This would be the case if the outer coating of the jar completely enclosed the inner coating, but in consequence of the projecting knob, &c., the charges are never quite equal in ordinary jars. Then if Q units of electricity enter the inner coating of the jar A from the electric machine, Q units of negative electricity will be induced on the outer coating of A, and, if we neglect the comparatively small charge of positive electricity which will remain on the outside of the outer coating of A, Q units of positive electricity will pass from the outer coating of A to the inner coating of B. Then, with the same qualifications as in the preceding case, we may say that Q units of negative electricity will be induced on the inner surface of the outer coating of B, and Q units of positive electricity will pass from the outer coating of B to the inner coating of C. Similar actions will take place between each pair of successive jars, and, finally, Q units of positive electricity will pass from the outer coating of F to the earth. (We have here spoken of Q units of negative electricity in order to avoid algebraical signs, but, in accordance with the one-fluid theory, we ought rather to have said — Q units of electricity.)

By this means we see that *all* the jars become charged with Q units of electricity, though only Q units are supplied by the electric machine. Had the jars been connected in the usual way, that is, with all their inner coatings connected together and all their outer coatings put to earth, to have charged each jar with Q units of electricity, it would have been necessary for six Q units to have been supplied by the machine; but we must not think that we have gained anything by the contrivance until we have investigated the potential of each coating.

The outer coating of the jar F is connected with the earth, and its potential is, therefore, zero. Let the potential of its inner coating be V, so that, C denoting its capacity, Q is equal to C V. Then, if all the jars are precisely equal in capacity, each will be charged to potential V, that is, the potential of the inner coating of each jar will exceed that of its outer coating by V. The potential of the inner coating of F is V, and the outer coating of E is connected with it. Hence the potential of the outer coating of E is also V, and since the potential of its inner coating exceeds that of its outer coating by V, it follows that the potential of the inner coating of E is 2 V. But this is also the potential of the outer coating of D, and D possesses the same charge—viz., Q units, hence the potential of the inner coating of D is 3 V. Similarly, we may show that the potentials of the inner coatings of C, B and A are 4 V, 5 V, and 6 V respectively. Hence the electric machine must be capable of producing a difference of potential between its prime conductor and the earth of *at least* 6 V *units*, and each jar can be charged to a potential only *one-sixth* that to which the machine could charge it by itself.

The energy of each jar will be $\frac{1}{2}$ Q V ergs, and the energy of the whole battery six times this, that is 3 Q V, and this is the electric work done in charging it. Suppose, now, that the inner coating of A is disconnected from the machine, and connected with the outer coating of F, all the other connections remaining undisturbed. The battery will then discharge itself, and Q units of electricity will pass across every section of the circuit. The case will be exactly the same as if a single jar of capacity only one-sixth that of each of the jars employed were charged with Q units of electricity, and, therefore, charged to potential 6 V, and the work done in the discharge will be $\frac{1}{2}$ Q · 6 V, or 3 Q V ergs, which is the energy of the battery.

Suppose that, the battery having been charged as before, the jars, remaining insulated, are disconnected from each other, and then placed with all their outer coatings connected to earth. Nothing will happen during this operation except the escape of the small free charge which is on the outside of the outer coatings of the first five jars, and which we have agreed to ignore, but the potential of the outer coating of each jar will, by the escape of this small free charge, be reduced to zero. The potential of the inner coating of each jar will then be V, and, being the same for each cell, the inner coatings may be connected together without any discharge taking place. The arrangement will then be equivalent to a single jar of capacity 6 C, charged to potential V with 6 Q units of electricity, and the work done in discharging it will be $\frac{1}{2}$ · 6 Q · V, or 3 Q V ergs, which is the same as before. A Leyden battery arranged in this manner may be said to be arranged *in multiple arc*, while the "cascade" arrangement may be said to be *in series*.

Suppose that one of the jars is charged to the full potential of 6 V. Its charge will then be 6 Q units, and its energy $\frac{1}{2}$ · 6 Q · 6 V, or 18 Q V ergs, so that if the electric strength of the glass is sufficient, a single jar may be charged so as to possess six times as much energy as the battery of six jars when charged in "cascade," or *series*, by the same machine. Of course, if the whole battery arranged in *multiple arc* be charged to the same potential, its energy will be six times that of a single jar, and, therefore, thirty-six times that of the same battery when charged in cascade. If the battery charged in multiple arc to the potential 6 V be discharged, the quantity of electricity which will pass in the spark will be six times the charge of each jar, that is 36 Q, while the length of the spark will correspond to a difference of potential of 6 V.

Suppose that the jars, having been charged independently, or in multiple arc to the potential 6 V, are placed on separate insulating stands, and then connected in series, the outer coating of F being put to earth, and its inner coating connected with the outer coating of E, and so on. Then each jar being charged to potential 6 V the potential of the inner coating of A will be 36 V. If the inner coating of A be now connected with the outer coating of F the whole battery will be discharged, but only 6 Q units of electricity will pass across each section of the circuit. The length of the spark will correspond to a difference of potential of 36 V. In this discharge, and in that last considered, the work done will be the same, viz.:—108 Q V ergs; but, with the battery arranged in multiple arc, the spark will be short and thick, corresponding to a transfer of 36 Q units of electricity, while,

Digitized by Google

with the battery arranged in series (or cascade), the spark will be much longer and thinner, corresponding to a transfer of only 6 Q units of electricity. In the nomenclature of last half-century the former would be called an arrangement "for quantity," the latter "for intensity."

When, as in the case of the Leyden jar, glass is employed as the dielectric of a condenser or accumulator, it is found that a connection sustained between the armature for a short time only does not suffice for the complete discharge of the instrument. Thus, if a Leyden jar be charged, and a metallic connection made between its coatings, the jar will appear to have been completely discharged; but, after leaving it to itself for a few minutes with its coatings disconnected, the jar will be found to have acquired a feeble charge, and if it be again discharged and left to itself, in course of time a further charge will appear. This phenomenon is known as *the residual charge of the Leyden jar*. At first sight it seems as if electricity had soaked into the substance of the glass, and required a long time to find its way out again.

Maxwell showed that the residual charge could be explained by supposing that the whole of the substance of the glass had not the same insulating power, but that it contained strata scattered through its substance, across which electricity could pass, though very slowly. As long as the jar remains charged there will, then, be true conduction currents taking place across these strata from the inside towards the outside of the jar. The effect of this displacement taking place in the interior of the glass will be to retain some negative electrification bound upon the outer coating, and some positive electricity bound upon the inner coating of the jar, after a connection has been established between the two coatings, and this will continue until the electricity has had time to return across the badly-conducting strata. On account of the feebleness of the force causing the return of the electricity, after the jar has been discharged, a much longer time will be required for the return journey than was occupied in the original displacement.

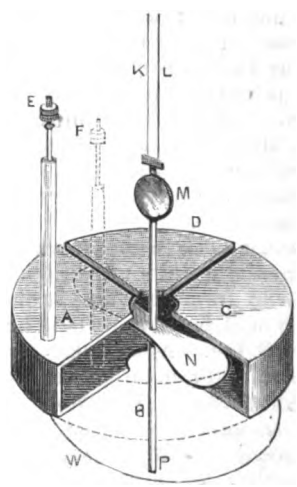
A phenomenon very analogous to the residual charge of the Leyden jar may, however, be observed in connection with the elastic properties of bodies. If a glass fibre be twisted and then allowed to free itself from the torsion, it will not return to its orginal condition at once, but, having in its first effort relieved itself of most of the twist, it will untwist itself through the remaining angles, only with extreme slowness, and, in the course of weeks, or even months, will not have returned to its original form, so that it is hardly too much to say that its condition at any time depends upon the whole of its past history. It is well known, too, that glass after being strongly heated does not at once return to its original volume on cooling, and Dr. Joule found that the zero of some of his thermometers continued to rise from this cause for more than twenty years. If we regard the energy of a charged conductor as due to an electric strain in the dielectric, we at once recognise a connection between these phenomena and the residual charge of the Leyden jar.

On the Quadrant Electrometer.

As previously stated, the immediate object of an electroscope is to *detect*, and of an electrometer to *measure* differences of potential. The gold leaf electroscope belongs to a class of instruments called by Sir Wm. Thomson *idiostatic*, because they contain no charge of electricity which is independent of the bodies whose difference of potential they are called upon to detect or measure. Such instruments can never be rendered very delicate, for when the difference of potential to be examined is very small, the charge of every portion of the instrument will be correspondingly small, and all forces called into play will be reduced in proportion to the square of the difference of potential between the electrodes of the instruments.

The quadrant electrometer belongs to the class of *heterostatic* instruments which contain a charge of electricity foreign to and independent of the bodies to be examined. As this charge can be increased to any extent consistent with the insulation of the instrument, the forces called into play can be made sensible even when the differences of potential are very small, these forces being, for any given charge of the instrument, proportional to the difference of potential to be measured, and not to the square of the difference.

The essential parts of Sir William Thomson's quadrant electrometer are represented in the accompanying figure. The needle N is a piece of thin aluminium, which is frequently corrugated to increase its stiffness. A small mirror, M, is rigidly attached to the needle so as to turn with it, and the whole is suspended by means of two single silk fibres, K L, the distance between which at the top can be regulated by means of a screw. This constitutes an ordinary bifilar suspension, the weight of the suspended body tending to cause it to set itself so that the two silk fibres are in the same vertical plane. From the bottom of the needle hangs a platinum wire which dips into strong sulphuric acid, which is contained in a glass vessel. The lower portion of the exterior of the glass vessel is partly covered with tinfoil, and this, with the inner coating of sulphuric acid, constitutes a Leyden jar, and serves to accumulate a large charge of electricity when the needle is charged. The sulphuric acid also keeps the instrument dry. The needle N is placed within a brass box consisting of four quadrants, A, B, C, D, each supported on an insulating glass pillar; but the quadrants which are diagonally opposite, viz., A C and B D, are connected by wires, of which the wire W, connecting the quadrants A and C, is shown in the figure. The quadrant B has been removed in the figure in order to show a portion of the needle. The binding screws in connection with the quadrant A and B form the electrodes of the instrument.



Sir W. Thomson's Quadrant Electrometer.

Before using the electrometer a positive charge is communicated to the needle N, the Leyden jar serving as a storehouse, from which the charge of the needle is replenished as it slowly escapes. A positive charge is preferable to a negative charge, because it is less quickly dissipated from the edges of the needle. The charge is communicated to the needle through an electrode which is made to touch the wire P, or to dip into the sulphuric acid in the jar. Before charging the needle, however, the bifilar suspension is so adjusted that the needle under the influence of the suspension and its weight alone takes up a position so that its axis is parallel to one of the divisions between the quadrants. While the needle is being charged all the quadrants are connected by a wire uniting the electrodes of the instruments. Then, after charging the needle, its position of rest should be the same as before. If this is not the case, there is a want of symmetry about the instrument which can be corrected by causing one of the quadrants, which is made movable for the purpose, to approach or recede from the centre by means of a screw. When the instrument has been properly adjusted the needle, though strongly charged, continues to point in the same direction as before. Now, suppose that the electrodes being disconnected from each other, the quadrants A and C are connected with the positive pole of a battery, and the quadrants B and D with the negative pole. Then, since the positively charged needle will always tend to pass from places of high to places of lower potential, it will tend to turn out of the quadrants A, C, and into the quadrants B, D. This tendency

Digitized by Google

will be resisted by the bifilar suspension, and the needle will take up a position in which it is in equilibrium under the action of the two opposing couples, and for *small* differences of potential the deflection of the needle will be *proportional* to the difference between the potentials of the two pairs of quadrants. The deflection of the needle is registered by means of a beam of light which is reflected from the mirror *m* and received on a graduated scale.

The quadrant electrometers made in Glasgow are furnished with an "idiostatic gauge," which indicates when the electrification of the needle has attained a certain degree, and thus enables us to keep the needle always charged to the same extent, and renders the observations made on one occasion comparable with those made at other times. It is also furnished with a "replenisher," by which the electrification of the needle can be slowly increased or diminished; but these portions of the instrument will be referred to later on.

A GUIDE TO PRACTICE IN THE SUBMARINE CABLE TESTING ROOM.

XII.

The operation of testing the joints in a cable is one that all assistants in a testing room should be able to perform, although the duty is, as a rule, confined to those employed in a cable factory. Some authorities are of opinion that this test is not so very important, whilst others maintain that it is of the greatest use. It is certainly included in the routine of testing in the various works, but among those electrical engineers who act as inspecting agents for the different companies there are some who have discontinued the practice of testing joints specially, considering that the insulation and capacity tests are sufficiently comprehensive to insure the safety of these points in the sentence which they pronounce on the cable generally.

A joint is a very critical portion of a cable, so many causes combining to make it difficult to insure perfection. A weak joint, in an insulating point of view, is like a bad link in a chain, it affects the quality of the whole length, and it must be remembered that there are some hundreds of them in a long cable, such as those between England and America.

As regards the value of a special joint test, it is said by those who do not consider it essential, that if an insulation test, applied at a proper time after the joint is made, gives the ordinary satisfactory results, there is no doubt that all is right, and that if any evidences of a fault are seen on first testing after manufacture it is safe to assume that the joint is the seat of it. They also say that the test is not *per se* conclusive, and it is true that a joint has been known to pass through the ordeal of the special test and yet to have afterwards proved to be imperfect; so that the reputation of the jointer who makes the joint is to some who are aware of this fact the best guarantee for its excellence where he is known to be a first-rate hand.

Without venturing to say that the joint test is altogether as satisfactory as some other tests, we would suggest that it is yet very useful, and that by taking every possible precaution, and carefully arranging all the details, leaving nothing to chance or possible neglect on the part of any one concerned, a weak joint will be detected, and we are at least sure that it has not gone though the machine, and so the evil is as small as possible. We make these remarks to impress on the learner the advisability of being particularly careful not to think this test a mere perfunctory duty; for here, perhaps, more than in other operations he ought to know what he is doing—that is, if the test is to be worth anything.

The goodness of a cable joint depends upon its insulating quality. It is made entirely by hand, and should be nicely rounded, and made as nearly as possible of the same dimensions as the core itself. It cannot be exactly the same, because the ends of the copper conducting wire must overlap each other, and are bound with other (fine) wire before being covered with gutta percha or other insulator employed in that core. The object being to test one short portion only of the cable, say eight inches indeed, particularly excluding every other item of its length if possible, some means in addition to the ordinary appliances for an insulation test must be adopted. Moreover, we have to test a section which has no end free—that is to say, the two ends of the joint are merged in the whole length, as far as it is concerned, and the only means of escape for any electrical charge (excluding all the rest of the cable from the consideration) is the insulating cover which has been laid on by the jointer. The charge, of course, is effected by connecting a battery to one end of the conductor, and the other end, or the end of the last length of core which has been joined on, is left hanging free, or sealed over, so as to be well insulated, as in the insulation resistance test. The learner will understand that these joints are made between the various lengths of core as they are united to the sheathed portion of the cable, or, more particularly, when a length is so far sheathed that a comparatively small portion is left behind the sheathing machine, a fresh drum of core is joined to this remnant in good time, that no unnecessary stoppage shall take place. These are called cable joints, as distinguished from what are termed "manufactured" joints, these latter being made during the preparation of the core in the "core department," and before it is wound on the drum. As a rule the "manufactured" joints are not tested on the "cable" side, though occasionally they are passed in the cable testing room; but they must be carefully distinguished from the cable joints when entered in the joint book, for reasons which will appear later.

We are only concerned here with the fact of the joint being made, and need not go into detail on the operation. It is necessary, however, to state that it is kept in water for some hours (generally six or eight) after it has been finished, and should not be tested till that time has expired. When made it is placed at the bottom of a trough containing water, this trough being mounted on an ebonite stand, and thus insulated.

The object of the test is to send a charge into the joint, and by maintaining this charge for a certain period, to discover whether the insulation is sufficiently good by noting the proportion in which leakage is permitted. So far it resembles an insulation test, except that we do not measure the resistance; but the leakage of charge is not allowed to pass directly to earth. It is caused to accumulate for the time fixed, and is then discharged through a galvanometer. In this part of its course it resembles the capacity test.

The means for observing the leakage through the covering of the joint is afforded by our former friend the condenser, which is brought into communication with the water in the trough, and collects whatever accumulation of electricity there may be due to that cause. This is afterwards discharged through the coils of a sensitive (mirror) galvanometer, and estimated in the manner explained in the capacity test, that is, by the deflection which appears on the scale.

There are various ways of joining up the different appliances for this test, and it can be taken either with a galvanometer or an electrometer. We shall show how to perform both operations, commencing with the former instrument. It will be as well to give two or three diagrams of connections for this first operation, beginning with one which sets forth the arrangement in a manner involving more connections than are absolutely necessary for the test, but these connections have been actually used in the joint-testing of many cables, and they show the principle and working of the operation more clearly than other arrangements which are more concise, though of course they are one and the same in their application.

This method of joining up for the test is shown in Fig. 23. A dividing line separates the portion outside in the cable shop and tank house from the connections in the testing room.

The pieces marked F and G are in the first place connected, the one to the cable (by the copper conductor) and the other to the trough. To the former, F, two separate connections can be made, that at A with earth and that at B with the battery. Thus, by depressing A alone the conductor of the cable would be put to earth; by depressing B alone it would be charged. Similarly, G has two separate contact pieces. C being put down connects the trough with the

Digitized by Google

galvanometer, and D, if put down, connects it to the condenser. If C and D were depressed at the same time, the condenser would be made to communicate with the galvanometer, and any charge which it contained would be discharged through the latter to earth. The earth connections are drawn separately here, but in practice they would probably be all joined to one earth wire. The learner will remember our remarks on the condenser in No. VI., and knows, therefore, why one pole of the condenser is put to earth. We shall see presently how the fact of the necessity for doing this helps to explain a feature in another arrangement of the joint test where no earth at all is used for any part of the circuit. This will come in its proper place presently. We will first give the outline of the test as now suggested, and afterwards the practical execution will be shown.

The trough containing water has two little hooks at the bottom to secure the joint, and is itself either a metal bath on an insulated stand, or if it be of insulating material as some forms are, it has a copper plate resting inside to which the leading wire connecting with the key G is joined. In the former event this lead is connected to the rim of the trough. In either case the object is to bring the key G into conductive communication with the water. If, now, B is depressed a charge enters the cable, and, of course, the joint also. We may regard the circuit as starting from one battery pole through the copper conductor and through the insulating cover of the joint to the water, but this being insulated leaves the circuit incomplete. The arrangement so far resembles the attempt to charge one pole of a condenser from a battery having one pole to earth, the condenser's other pole being insulated. But if D were depressed at the

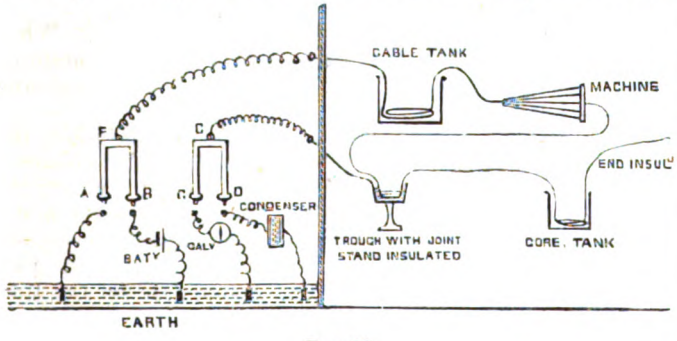


FIG. 23.

same time as B, the condensor is joined up to the trough' and any electricity leaking through the joint would pass to one side of this accumulator, which would retain the charge until, on putting down C, it would be discharged through the galvanometer thus connected to it on one side and to earth on the other.

In speaking of this course as a circuit we must recall to the learner's attention the remarks in Nos. VI. and VII., where the condenser was discussed. Referring also to the insulation resistance test in No. IX. we desire to remind him that the view of its conditions there suggested was proposed as being the simplest that he could take at the time; and it seems necessary to observe that the apparent difference in the principles involved in these different tests is *only* apparent. It will be safest to regard the joint test as in one view resembling an insulation test, and in another being more like that for capacity, and to consider the action as involving a charge by which an inductive as well as a conductive circuit is produced. If the condenser were cut off from the trough through the key D being raised there would be facility of accumulation as far as the joint is in question. The charge being continued from the battery would be acting throughout the length of the cable as in the ordinary insulation test, and we could not say there is any current through the cover of the joint. As a matter of fact, the key D is kept down all the time that the battery is charging the cable, and whatever quantity of electricity accumulates in the condenser certainly comes from the joint. The rest of the cable is, no doubt, under water in its tank except that part which is being sheathed, and that which is only core, but we need not regard this at present. There is no supposed question of the leakage at any point except at the joint. When C is put down the galvanometer will show by the deflection whether the leakage is too great, a limit being fixed which ought not to be surpassed. The depression of the key A after this will finally discharge the cable, the battery being previously taken off by releasing B. This outline must now be filled in by going more in detail through the test, in which there are other features of importance also concerned with points which have given rise to various opinions on its theory.

Whilst the plan of connections in Fig. 23 is very simple, it is possible that the arrangement on the table may not outwardly resemble it. But if the operator had to join up the various parts himself, he would easily find the points which we have marked with letters, even if the other details were covered. By remembering the relations between the several points, and where each should lead to, no difficulty need remain.

Like the other tests which have been considered, this is comparative, and a well-defined standard is fortunately provided. It is agreed that a joint shall prove as good in point of resistance to leakage as (say) six feet of the core with which it is united. When a piece of this length is submitted to the test before us a certain deflection is produced on the scale, and the joint must not cause a larger deflection when tested in its turn. As regards the number of divisions allowed for this deflection the limit will depend on the sensitiveness of the galvanometer. This, again, is controlled by the position of the large directing magnet above the cover, and also by other considerations. In practice the beginner will find all this properly prepared. Some electricians arrange for a deflection of 1 or 2 divisions only with certain cores, and others prefer a wider range; we cannot fix any definite limit here. In the next number we have to consider the test as it would be gone through practically, referring to Fig. 23 for fuller explanation where any diagram shows only a part of the connections.

CROMPTON'S COMPOUND MACHINE.

BY GISBERT KAPP.

(CONTINUED FROM PAGE 155.)

In order not to complicate the question more than necessary, we will assume the field to be separately excited, and always to the same intensity. If no current traverses the armature there will be no curl distorting the primary lines of force, and no secondary lines of force at all. The points of greatest polarisation in the revolving Gramme ring will be shifted forward by a certain angle on account of the time required by the iron to take up and lose magnetism; but, as Breguet's experiments show,* this angle is very small, and, being constant for all currents, need not be further taken into account.

We will also assume that the core (as should always be the case in a well designed machine) is so constructed that local currents in itself, the curl from which might shift the field, are avoided. Under these conditions we find, then, that the diameter of commutation should be very nearly horizontal, and if the brushes were set with a certain lead we should expect them to spark heavily. Experiment shows, however, that this is not the case. The apparent anomaly can easily be explained if we remember that the so-called neutral points (that is, those points where the number of primary lines of force is a maximum) in the Gramme ring are in reality not points at all, but zones of some extension, and consequently a certain variation from the theoretically best position of the brushes can be allowed.

The presence of these neutral zones must in so far be regarded as an evil, as the coils that pass them, whilst contributing their full share to the total resistance of the armature, contribute nothing to its electromotive force. But the evil is a necessary one, for if an attempt were made to reduce the neutral zones to two points by extending the pole pieces, so as to envelop more of the circumference of the ring, it would be found that some of the primary lines of force,

* See *Electric Illumination*, p. 86.

Digitized by Google

instead of deviating into and out of the ring, run straight across between the extended pole pieces, and are thus lost.

That this is actually the case the author has recently had occasion to prove by an experiment upon a Bürgin machine, the electromotive force of which was increased by 9 per cent. (from 75 to 83 volts) through cutting a quarter of an inch off the extension of pole pieces.

Admitting, then, that a neutral zone is a necessity, our primary curve (see Fig. 4, page 155) is not correct, but should be more of the shape shown in Fig. 5. It will be seen that as long as the brushes are shifted within the neutral zones represented in the diagram by the spaces where the curve coincides with the axis of abscissæ, no appreciable change in current or electromotive force will take place. Anywhere within that space the brushes are in the right position. The same holds good if a very small current be allowed to traverse the armature, for there will be so few of the secondary lines of force that their curve can practically be considered to coincide with A X.

The area contained within the primary curve and the axis of abscissæ gives, therefore, without any deduction, the electromotive force between brushes B_1 B_1.

If, now, a moderate current be allowed to flow through the armature two things will happen. The primary curve will be shifted forward in the direction of movement, which in the diagram is equivalent to shifting the brushes to the left, say to B_2 B_2; and the secondary curve, instead of coinciding with the axis of abscissæ, will deviate from it above and below. The electromotive force is now represented by the area contained between the two curves. Something has been added to and something subtracted from

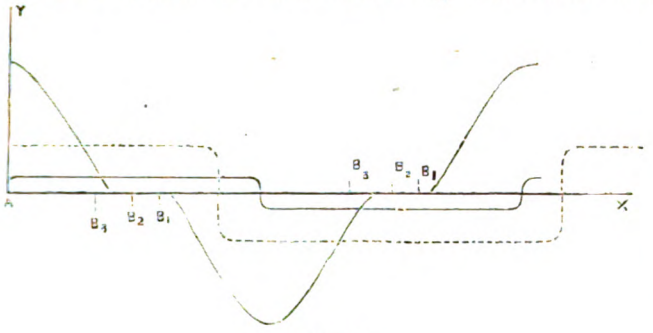

FIG. 5.

the area which represented it before. From the diagram, which it must be remembered is not to scale but merely an illustration of the idea, it would hardly be safe to predict whether the total result will be an increase or decrease of electromotive force. Roughly speaking, we may expect that, with moderate currents, the total effective area will not be materially altered; for, as long as the field is only slightly shifted and the brushes remain within the neutral zone, the secondary curve, which must necessarily be of the somewhat rectangular character shown in the diagram in a full line, adds as much on one side as it takes away on the other.

With very heavy currents, however, the case is different. The field gets shifted to such an extent that the brushes come to stand outside the neutral zone on the inclined part of the primary curve, say at B_3 B_3; and in this position the area subtracted by the secondary curve (dotted in Fig. 5) exceeds that added.

If the reader will take a piece of tracing paper, draw on it a secondary curve, and shift it along A X, he will get a very clear idea how the electromotive force varies with different degrees of distortion in the primary field.

If the above reasoning be correct, we should expect to find that in a separately excited field the electromotive force in the armature is very nearly independent of the current as long as the latter remains within moderate limits, but that it decreases as soon as the current is allowed to increase beyond these limits.

And this is exactly what happens in practice.

Fig. 6 represents the characteristic curve of an ordinary Bürgin series dynamo (not a compound machine), designed for a maximum current of 40 amperes. Scale of diagram:—1 volt and 1 ampere equals 1 millimeter, but to economise space the ordinates are drawn too short by 100 volts. If we now excite the field of this machine separately and to the same intensity as represented by the abscissæ of the characteristic curve, and measure the electromotive force of the armature, but without taking any current from it, we find a new characteristic curve which coincides with the former curve for all currents between nine and seventeen amperes, but beyond that rises considerably above it. It must here be remarked that in determining these curves experimentally, care must be taken to keep the speed of the machine as constant as possible. But, in spite of all precautions, slight variations in speed will very often occur. The reading for E.M.F. must then be corrected by assuming it to be proportional to the speed. This is correct if done within reasonable limits.

It was shown in the beginning of this paper that to maintain a constant difference of potential in the external circuit E a, the electromotive force in armature should increase with the current. But now we find that instead of doing this it actually decreases if the field be kept constant. This behaviour is very inconvenient for regulation, and the question now arises, how can the evil be avoided or minimised? The theory of primary and secondary lines of force, as developed above, supplies without further need for investigation an answer to this question. There are two remedies. We can either keep a small neutral zone, and prevent excessive distortion of the field, or allow the distortion and provide a neutral zone wide enough for it. In practice I have found a combination of both to give the best results. Distortion of the

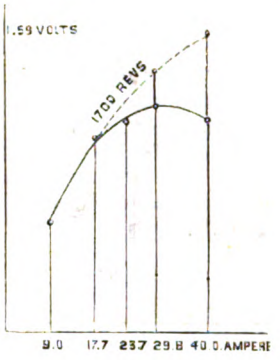

FIG. 6.

field can only be prevented by putting more primary lines of force into it, and this again requires that there should be more iron than usual in the pole pieces and arms of field magnets. In the Crompton compound machine, this is done by making the arms twice as long as those of an ordinary Crompton-Bürgin machine, and the pole pieces by about 30 per cent. heavier. The increase of length has also this advantage, that it is possible to obtain the necessary excitation (ampere turns or coil amperes) with a thicker wire, and as for equal ampere turns the resistance is inversely proportional to the weight of copper employed, it follows that the lengthening of magnets has the additional advantage of reducing their resistance.

Let R be resistance of armature, r that of main coils and external circuit, ρ that of shunt coils; and let c be the external, γ the shunt, and $C = c + \gamma$ the total armature current, then we have

$$E\,b = r\,c = \rho\,\gamma.$$
$$E\,a - E\,b = R\,C$$
$$E\,b = \frac{E\,a}{R\left(\frac{1}{R} + \frac{1}{r} + \frac{1}{\rho}\right)}.$$ *

If the main current is led in n turns round the field mag-

* If we suppose $\rho = \infty$, that is an infinite length of shunt wire, the above formula can be simplified to $E\,b = \frac{r\,E\,a}{R + r}$, which is that given by Mr. Bosanquet. This formula is, therefore, only correct if it be permissible to neglect altogether that amount of current which goes through the shunt coils. In ordinary cases this amount is, however, too large to be neglected.

Digitized by Google

nets its existing power can be expressed as $n\,c$ ampere turns. Similarly, if the shunt current is led in v turns round the field magnets its share in the work of exciting can be expressed $v\,a$ ampere turns.

The intensity of magnetism will therefore be a function of

$$\text{ampere turns} = n\,c + v\,\gamma;$$

or if we eliminate c and γ,

$$\text{ampere turns} = \left(\frac{\mathrm{E}\,a}{\frac{1}{\mathrm{R}} + \frac{1}{r} + \frac{1}{\rho}}\right) \cdot \left(\frac{n\rho + v r}{\mathrm{R}\,r\,\rho}\right)$$

From this formula it will be seen that the exciting power of both coils is directly proportional to the electromotive force in the armature, and as that itself is a direct measure for the magnetic intensity of the field, we can say that in a given machine, as long as all resistances remain unchanged, the ampere turns are a direct measure for the electromotive force. If, for instance, the E a for a certain speed and ampere turns were known, then by inserting dynamometers or ammeters into the shunt and main circuit, and observing both currents and corresponding ampere-turns for different speeds, the electromotive force due to each speed can easily be calculated. In this respect the compound machine is exactly like a series dynamo.

If we now assume that the external resistance r varies, the case becomes at once very complicated. In the first place, the ampere turns are altered, and, consequently, the exciting power; this affects the intensity of the magnetic field, but not in a simple ratio. The nearer the field magnets are to the point of saturation the smaller will be the influence of a variation in the exciting power, but, whatever the amount, it affects in a direct ratio the total electromotive force, which in its turn again alters the exciting currents until, by a system of mutual reaction, a state of equilibrium is again established. The action is so complex that there is very little inducement to investigate it analytically, as only a maze of most complicated formulæ, with no visible way of solution, can be expected; but, by resorting to a graphical method, the investigation is in no way difficult.

(TO BE CONTINUED.)

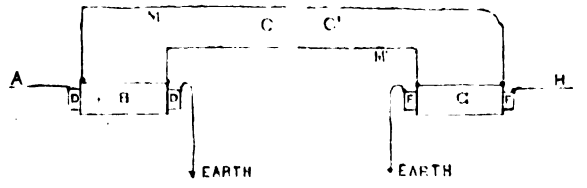
LONG-DISTANCE TELEPHONY AND BENNETT'S TELEPHONIC TRANSLATORS.

Shortly after the Postmaster-General had won his famous test case against the United Telephone Company, licenses were granted to the various companies throughout the United Kingdom to open local exchanges, but the privilege of joining the systems of two or more different towns was absolutely denied them, however important or desirable communication between them might chance to be from a commercial point of view.

The exchanges opened by the National Telephone Company in Glasgow, Greenock, Dumbarton, Paisley, Hamilton, and Coatbridge may be taken as an illustration of the difficulty. The business relations between these centres are of the most intimate nature, it being not uncommon for one firm to possess branch works or offices in two or more of them, and daily customers in all, and yet the company was not permitted to erect anything but local exchange lines.

But after some negotiation the Post Office consented to provide trunk wires on their own poles between the various exchanges, stipulating that a separate trunk wire should be erected for every eight subscribers desirous of availing themselves of the privilege, and for every trunk wire the company should pay the Government an annual rental of £320 between Glasgow and Greenock, £104 between Glasgow and Paisley, £128 between Glasgow and Hamilton, and £120 between Glasgow and Coatbridge. Subsequently a trunk wire was projected between Glasgow and Edinburgh, for which the Government tax was fixed at £560 per annum. Similar arrangements were made for Leeds, Bradford, Huddersfield, Birmingham, Wolverhampton, and other important towns, and, notwithstanding the heavy rates which the Government tax rendered necessary, amounting in the case of Edinburgh to no less than £110 per annum for each subscriber, the leading manufacturers and merchants were not slow in taking advantage of the opportunity of obtaining free communication with their distant works and customers. But now arose a difficulty which, perhaps, may have been overlooked by the Post Office electricians, and certainly by the officials of the National Telephone Company by whom the negotiations were conducted. Being erected on the same poles as the ordinary telegraph wires, the new trunk lines would obviously be greatly affected by induction. This was recognised, and it was agreed to run metallic circuits on the principle first suggested by Professor Hughes, and first given practical effect to by Messrs. Moseley and Sons, of Manchester. This plan was, of course, known to be effective in neutralising the effects of induction from neighbouring telegraph wires, but until the contract with the Post Office was nearly, if not quite, completed, no person had considered how the extremities of the metallic loops forming the trunk lines were to be connected when required to the subscribers' single local wires.

Putting the metallic loop to earth anywhere would be to destroy its efficacy, while it was quite impossible on the score of expense to run metallic loops for the local subscribers, as that would mean doubling the company's already crowded systems. When the terms of the contract came to the knowledge of Mr. Alfred R. Bennett, engineer to Messrs. D. and G. Graham, the National Telephone Company's engineers and contractors for the Glasgow district, he pointed out the hitherto unseen rock ahead, and was requested to devise a means of overcoming the difficulty. In May, 1881, Mr. Bennett began to experiment, and, after trying several plans, patented the only one which promised success. This consists of a system of induction coils of peculiar construction, arranged to repeat or translate the telephonic pulsations to and from the metallic loop without putting it to earth at any point. Having induced currents of small quantity to deal with, it was evident that coils having primaries of the usual thick wire and small resistance would not answer. Coils with primaries and secondaries of equal gauge and resistance were therefore tried, but it was afterwards proved that the best results were obtained from coils having a resistance ratio of 1 to 2·6. The connection between the metallic circuit and the single wires may be understood from the annexed figure:—



A leads to switchboard and subscribers. B indicates Glasgow Exchange.
C C' is a metallic loop 50 miles long. G indicates Greenock Exchange.
H leads to switchboards and subscribers.

One of the coils of the translator at the Glasgow Exchange is connected by means of the metallic trunk loop, which in this case has a total length of 50 miles, with one of the coils of the translator at the Greenock Exchange. When a Glasgow subscriber wishes to speak to a Greenock subscriber their respective single wires are joined to earth through the switch-boards and the disengaged coils of the translators. The speaking is then transmitted in the following manner:—

(1) The current arriving at the Glasgow Exchange from the first subscriber's wire A passes through the coil D D of the translator to earth; and

(2) Induces in the other coil B of the translator similar currents, which pass over one wire of the metallic loop through the coil G of the Greenock translator, and back to Glasgow by the other wire of the loop; and

(3) Induces similar currents in the other coil F F of the Greenock translator, which pass away to the second subscriber's wire H, *viâ* the switch-board, and to earth through

Digitized by Google

his telephone, the other end of the coil F F being to earth at the exchange.

M and M′ are magneto-electric calls and bells, inserted one in each wire of the metallic loop, for the purpose of enabling the exchanges to attract each other's attention.

Although some diminution in the loudness of the speaking results from the double transfer by induction to and from the metallic loop, this can be compensated for by speaking closer to the transmitter, or more distinctly than is usual on local lines; or by using two or more cells joined for quantity on the transmitter instead of the ordinary single cell. Curious features of this apparatus are that the current is changed no less than four times between the speaker's transmitter and the listener's telephone, and that induction is successfully used in one form to combat the evil effects of the same phenomenon in another. In the Glasgow district the invention, which is now the property of the Electromotive Force Company (Limited), has been working successfully for about nine months, and for a shorter period in Staffordshire, Warwickshire, and Yorkshire. Its sphere of usefulness will, doubtless, enlarge as telephonic intercommunication between distant towns becomes more common.

THE (ELECTRIC) CONDUCTIVE AND INDUCTIVE CIRCUITS GEOMETRICALLY ILLUSTRATED.

BY F. C. WEBB, M.I.C.E.

(CONTINUED FROM PAGE 178.)

In the figures already given, we see the general action which takes place when trying to work through a long submarine cable, or subterranean wire. When a battery is applied at A an appreciable time elapses before the current at B arrives at its maximum, and even if we can work with the current arriving at B before it arrives at its maximum a certain time must elapse. Then, if working with a single current, a certain time elapses before the dynamic charge is discharged, and during the discharge the current at B continues to flow, though getting less and less, as shown by the

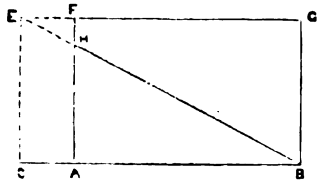


FIG. 42.

curves, thus continuing the signal after we wish it to cease. By sending a reverse current the charge is, of course, more rapidly neutralised, a system always adopted. The proportion which the dynamic charge, when the current has arrived at its permanent state (or maximum at B) to the total static charge the line would take, with the same battery, if the distant end B is insulated, is shown in Fig. 42, where C A is the resistance of the battery, C E the electromotive force, A F C B would be the charge with the end insulated, and A H B the dynamic charge when the end is to earth. Thus, if we call R the resistance of the line, r the resistance of the battery, and E the electromotive force, then as we suppose the electrostatic capacity to be proportional to the resistance, E by R would be the static charge, the charge in this case being independent of the resistance of the battery. For the dynamic charge we must find the potential at A, and we have B C $(= r + R)$: C E $(= E)$ :: A B $(= R)$: A H $(=$ P potential at A when B is to earth); or, in fact $\frac{E.R}{r + R} = P$, and evidently A B × A H divided by 2 is the triangle A H B. Whence $\frac{E R}{r + R} \times \frac{R}{2}$; or $\frac{E R^2}{2 (R + r)}$ equals the dynamic charge in terms of the static charge.

If the battery resistance is very small in comparison to any two lengths of similar wire, then the dynamic charges in them with the same battery will be nearly directly as their lengths as seen in Figure 43, where C A is battery resistance, C E electromotive force, A B one wire, and A D another. The charge in A B is A F B and the charge A D is A G D.

If, on the contrary, the resistance of the battery is very great in proportion to the resistance of two different wires, then it will be seen that the charges are nearly to one another as the squares of the lengths. For by Fig. 44 the greater C A is in relation to A B and AD the more nearly lines E B and

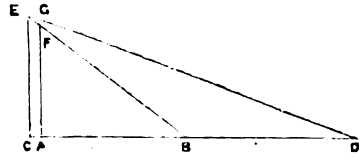

FIG. 43.

E D approach to parallelism, and if those lines were parallel, then the triangles A F B and A C B would be similar, and consequently proportional to the square of their homologous sides, or, in fact, to the squares of their lengths.

If the current is the same in two wires of different lengths, but similar type, then the dynamic charges will be exactly as the squares of their lengths, as seen by Fig. 45. When A B and A D are two wires, C E being the electromotive force of the battery applied to A B and C A its resistance, C′ E′ the

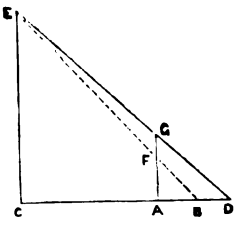

FIG. 44.

electromotive force of the battery applied to A B, and C′ A its resistance—these electromotive forces being made proportional to the two wires, so as to produce the same current in each—then the line of potential in A D will be G D and in A B it will be F B. The charge in A B is A F B and in A D A G D. And as F B and C D are parallel (since they represent the same current) by the reasoning before given these charges are to one another as the squares of their lengths.

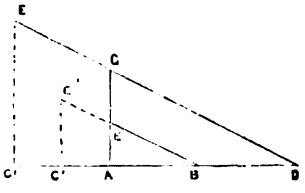

FIG. 45.

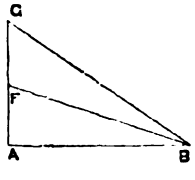

FIG. 46.

In any one wire the dynamic charge will be directly as the *current* producing it, as seen by Fig. 46, where, if the potential line of the larger current is represented by G B and the lesser by F B, the currents are evidently directly as the potential at A, no matter how that potential is produced (as regards resistance of battery, &c.), and the charges are as these potentials A F and A G.

WESTERN UNION TELEGRAPH COMPANY.—The Union Trust Company of New York give notice that, in accordance with the provisions of the deed of trust executed by the Western Union Telegraph Company, under date of February 1st, 1875, to the Union Trust Company of New York, as trustee, certain bonds were drawn by lot, on the 5th inst., for redemption on the 1st day of March. The numbers, &c., can be ascertained, and the bonds will be paid at the office of Messrs. Morton, and Rose, Company, Bartholomew-lane, E.C., on and after the 1st March.

1882.

Last week we ended our review of the year with a reference to what the Post Office has done in the way of establishing telephone exchanges. This week we may therefore fitly take up the threads of our subject by referring to private telephonic enterprise. In our review of telephonic work for 1881 we said "the progress made by the telephone during the past year has been extraordinary, and we may look for even greater advances in 1882." This forecast, which we may remark was a very safe one, has been amply verified.

The great event of the year has been what by common consent is called "The Telephone Case," though, in reality, several separate actions have been tried. The first note of battle was sounded in Edinburgh early in the year, when the United Telephone Company brought an action on the 25th of January last against an electrician named Alexander Maclean, of Edinburgh, for the infringement of Patent No. 2,909, July, 1877, taken out by Edison, and Patent No. 4,765, December, 1877, taken out by Graham Bell, through his agent, Morgan Brown. The defence was mainly that neither patents were good, as the instruments therein described had been previously made public, Edison's by Reis in 1863, and Bell's by several papers in 1876. The result of the trial was that Lord McLaren, the judge, gave judgment for the plaintiffs, and upheld the infringement of their patents. Subsequently the same company brought an action against Messrs. M. Theiler and Sons, of London, for infringing the Edison patent (this was tried on 2nd March), and a perpetual injunction was obtained.

Later on (24th April) the same company brought another action against Messrs. Harrison, Cox-Walker, and Co., of Darlington, alleging that they had made and sold three instruments which were infringements of other patents, viz., the Cox-Walker and Hickley receivers, which were said to infringe the Bell patent, and the Hunnings transmitter, which was said to infringe the Edison patent. This case was tried before Mr. Justice Fry. We need not refer here to the voluminous evidence given by electricians, from Sir William Thomson downwards, which will be found recorded in our last volume. Suffice it to say that Mr. Justice Fry decided that the defendants had infringed Bell's patent, but that Edison's patent was invalid because he had included in the provisional specification an invention, the phonograph, which was not mentioned in the complete specification, and, therefore, the plaintiffs were not entitled to an injunction as regards this patent. On May 25 the same company brought an action against Messrs. Orme and Co., of 5, Barbican, E.C., to restrain them from selling or using the Hickley telephone, and obtained an interim injunction.

In the month of June, the case of the London and Globe Telephone Company *v* the United Telephone Company came before Mr. Justice Fry. This was a motion to restrain the defendants from publishing the following notice on the cover of their subscribers' lists, viz.:—"The United Telephone Company have been advised by eminent counsel that all forms of transmitters in which carbon is used in a free or powdered form, as, for instance, in the transmitters usually known as Moseley or Hunnings, and that all the so-called microphone transmitters, including those known as the Crossley and Gower-Bell, are infringements of Mr. Edison's patent as amended by disclaimer," and a further notice to the effect that the United Company would proceed against any one making and selling such transmitters. It may be mentioned here that the London and Globe Company were assignees of the Hunnings transmitter. The result of this case was that an injunction was granted against the United Company, restraining them from issuing any such notice without a reference to Mr. Justice Fry's decision in the case of the United Telephone Company *v* Harrison, Cox-Walker, and Co., so long as that decision remained unreversed.

In the meantime the United Company had lodged a disclaimer of the phonograph, as described in Edison's provisional specification mentioned above, which was allowed by the Attorney-General and Mr. Justice Fry's decision on the patent as disclaimed was on all points in favour of the company. Four more actions were, however, brought by the United Company, one on the 25th July against Messrs. Cox and Williamson, of Plymouth, with reference to the Cox-Williamson transmitter and the Ader receiver, the result of which was in favour of the plaintiffs. Another against Mr. E. Butler, of 71, Lord-street, Liverpool, for infringing Bell's patent, on the 17th November, when the

Digitized by Google

company obtained a perpetual injunction with costs; another against Mr. Haines, of Birmingham, for infringing both Edison's and Bell's patents, which was also tried on the 17th November, and in which the company were again successful; and yet another, against Messrs. Hebden and Co., of Bradford (Yorks.), on the 15th December, for infringing the Bell patent. In this case, also, the company obtained a perpetual injunction. So that, practically, the United Telephone Company have, after much litigation, made themselves masters of the situation for the present; and with this we will take leave of the legal vicissitudes experienced by the telephone during 1882.

There have been a great number of improvements, or so-called improvements, in telephonic apparatus patented during the year, and a few of these improved telephones have been exhibited. We are not aware, however, that they have been practically adopted to any great extent. In our 1881 review we mentioned that apparatus had been devised by means of which one line wire only would be needed for several subscribers. This apparatus was shown in the early part of the year, under the name of the inventors, Messrs. Brown and Saunders, at the Crystal Palace Exhibition, and a full description of it was given in our columns. In May, Professor Dolbear, one of our American cousins, read an interesting paper before the Society of Telegraph Engineers and of Electricians, in which he described his experiments in telephony and his new telephone receivers, which are based on the principle of induction, patents for which have recently been published. In the course of the discussion on Professor Dolbear's paper, Mr. Willoughby Smith gave some account of experiments that he had been making in the same direction, which culminated in his "inductophone," described in our issue of June 3. Mr. Smith's apparatus consisted of a large flat coil of insulated wire placed in a frame like a looking glass, and connected in circuit with a battery and a tuning fork, between the prongs of which is a small electro-magnet. The fork carries on one prong a small contact piece, which makes and breaks contact with a disc carried by a binding screw at the end of the fork. The current is arranged to have a make and break contact in the main circuit. When a current is sent through the flat coil above mentioned, lines of force radiate from it as from a short electro-magnet, and by bringing the tympanum of an ordinary Bell telephone in the field of force thus obtained, the effect was that the sound of the vibrating tuning fork was reproduced. It was noticed that the sounds could be obtained in the next room; indeed, nothing could be found through which the lines of force would not pass and and affect the telephone. We may quote here our remarks on this discovery:—"These experiments of Mr. Willoughby Smith prove that the receiving telephone may be altogether independent of the circuit of the sending instrument, so far as regards visible and material connections."

Another interesting achievement of the year was that accomplished by M. Van Rysselberghe, of the Brussels Meteorological Observatory, who succeeded in sending telegraphic and telephonic messages a considerable distance along the same line, with good results at the receiving station. This was accomplished by a method which has since been patented by the inventor, and consists briefly in interpolating a condenser in a shunt from the circuit, so that the line wire does not become suddenly, but slowly, charged; and, therefore, the induced current will be equally slow and progressive. So that instead of a series of violent and instantaneous attractions of the telephone diaphragm, produced by rapid charging and discharging of the line, we have a series of progressive and weak movements, which do not interfere with conversation, at least so the inventor claims. As the English patents relating to this invention are now published, possibly the coming year may witness some practical illustration of this principle in our own country; though, from all accounts, the telephone authorities here are not very enthusiastic about this system. During the year Captain M'Evoy has patented what has been called "a submarine detector," in which the telephone plays an important part. It consists of a box containing two coils of wire, and a make and break contact, and a telephone. From this leads a small cable containing four insulated wires, to which is attached another box containing two more coils. The four wires and the two sets of coils, &c., form two circuits, a primary and a secondary, the telephone being in the secondary circuit. A battery being connected to the primary circuit, the coils are adjusted until little or no noise from the make and break arrangement is heard in the telephone. The small box and cable is then let down into the sea or river, and on coming near to any metal body a loud noise will be heard in the telephone. As will be seen, this is simply an application of Professors Hughes and Bell's experiments to this class of work. The telephone has been tested for diving work during the year by a committee of French naval officers, with good results It has also been experimented with for the same purpose by Mr. H. H. Wake, engineer to the River Wear Commissioners, assisted by Mr. A. W. Heaviside, of the Postal Telegraph Service, at the South Dock, Sunderland, signals being exchanged between the occupant of a diving bell under water and men in a barge at the surface. Here, again, the results were satisfactory. A few experiments have been carried out on the continent, in America, and at home, with underground telephone cables, the results of which have been stated to be satisfactory. At present, however, overhead wires are the rule, and seem likely to continue so, if we may quote Mr. W. H. Preece's opinion, as given in his paper before the British Association last year. He says, "The use of underground wires very seriously impedes telephonic extensions, and with our present apparatus and present knowledge we cannot readily speak over greater distances than 20 miles." Let us now glance at the present position of the various telephone companies, and note the progress the telephone has made in public opinion since 1881. To begin with, we may take the

United Telephone Company, of Coleman-street, E.C. This Company has been in existence for two years and three-quarters; its progress during the year will be seen at a glance from the following monthly returns of new subscribers. Thus, in January last 98 new subscribers were coupled up; in February, 93; March, 94; April, 93; May, 94; June, 113; July, 71; August, 66; September, 67; October, 87; November, 81; December, 71; or 1,028 during 1882, raising the total number of subscribers now actually connected up to 2,247. The company now has seventeen exchanges in full working order distributed throughout the metropolis. The calls, which in July last averaged about 14,000 a day, now amount to nearly 20,000, or, allowing one answer for each inquiry, 40,000 messages per day. Last year we mentioned that *The Times* utilised this company's system to verbally transmit the speeches of members of the House of Commons to its office in Printing House-square. *The Times* found the telephone so useful that it now makes use of two wires in place of the one originally employed. The *Freeman's Journal* also has adopted the same means of communication between its offices in the Strand and the House of Commons. The company hopes soon to be able to run lines between London, Liverpool, Manchester, and Birmingham. Within the last few days we chronicled the fact that they had "got through" successfully to Brighton, and that conversation had been carried on between their London and Brighton Exchanges. As a license to connect the metropolis with London-by-the-Sea has been granted by the Postmaster-

Digitized by Google

General, we may hope shortly to hear that regular communication has been established between the two. Many newspapers are availing themselves of this company's system, and amongst them we may enumerate *The Observer* and ourselves.

In the provinces the telephone is being adopted with that leisurely appreciation of an innovation, even though pre-eminently useful, which so markedly distinguishes the stolid Briton from his more go-ahead brother in the States. In addition to its metropolitan business, the United Telephone Company has exchanges in Bristol, with 236 subscribers, and Brighton, with 58. Private telephone lines have also been erected by this company in Plymouth, Portsmouth, Southampton, and Cardiff, as well as Norwich and Ipswich, at which two latter towns exchanges are about to be opened. We also hear that the company are selling a concession to use their instruments in the south of England to a company which will be known as "The South of England Telephone Company." The chief company having exchanges in the country is the

National Telephone Company, whose head office is at 11, Queen Victoria-street, E.C. The progress made by this company during the last year or so will be readily gleaned from the following statistics, which have been supplied us by the courtesy of the company's secretary:—

Statement of Subscribers—National Telephone Co.

Note.—These numbers include exchange and private line subscribers.

The Oriental Telephone Company has had a somewhat exceptional experience during the year, seeing that the breaking out of war in Egypt surprised its agents in Cairo and Alexandria just as they were at their busiest. As has been recorded in these pages, however, the lines and instruments of the company proved of the greatest use to our officers, more particularly at Alexandria. It must have been as much of a surprise as a pleasure for the company to receive a letter from their agent in this town so recently as November last to the effect that telephonic communications were almost completely reinstated, and that notwithstanding the turmoil and uncertainties of war they had "virtually not lost a subscriber." The company have very recently sold their interest in Bombay and two other neighbouring Indian States to a local company known as "The Bombay Telephone Company." According to the latest figures the following represents the present *clientèle* of the company. At Alexandria they have 94 regular subscribers, 21 Government subscribers, and had, at the date of our information, applications from 17 more, or altogether 132. At Cairo they have 60 subscribers. Bombay, before the sale to the local company, contributed 81, Calcutta 108, Madras 34, Rangoon 36, Kurrachee 15, Colombo (Ceylon) 30, Singapore 70, Hong Kong 15, and Shanghai 73. At Honolulu the company have more subscribers than at any other exchange, viz., 289, which gives them a grand total of 943.

We had hoped to have given particulars relating to Messrs. Tasker, Sons, and Co.'s exchange at Sheffield, and the Lancashire and Cheshire Company's exchanges at Liverpool, Manchester, and elsewhere, but have not yet received the necessary information.

THE LATE MR. C. V. WALKER.

The death of this well-known practical electrician, which we announced in our last issue, and which took place on Christmas eve, will recall to many minds the early days of telegraphy and the struggles it had to engage in before it became the indispensable servant of the public. Mr. C. V. Walker's name is intimately associated with those struggles, and although he was never in the foremost rank of promoters or inventors, his active and intelligent assistance to the cause of telegraphic enterprise at the most trying period of its history will ever entitle him to an honourable place by the side of the great pioneers. For nearly forty years, and down to the time of his decease, Mr. Walker had been in the service of the South Eastern Railway Company, for the greater part of the time as their manager of the telegraphs. It was on this line that he assisted Mr. Cooke in erecting its first telegraph wire, and ever since then his labours have been unceasing in maintaining and perfecting the vast and important system of wires which have grown upon that line of railway. Railway telegraph signalling was of course his chief care, the block system by means of electric bells having been first introduced by him on this line, to be superseded by visual signals later on, in 1863-4. Many years previously Mr. Walker had used gutta percha covered wire for underground telegraph wires and for wires carried through tunnels. The credit of being the first to use gutta percha insulated wire for such purposes, we believe, belongs to him. This was in 1847. The following year an experiment of far greater import was successfully carried out under his direction. He was the first to perform the feat of laying a telegraph cable. From a ship stationed a couple of miles or so off Folkestone Mr. Walker signalled a message to London, the cable from the ship being joined to the land lines on Folkestone beach. This took place on October 13, 1848, which is a day deserving of being remembered, especially in connection with the veteran electrician who has now gone from among us. Several valuable inventions, or rather, we should say devices, connected with train signalling are due to Mr. Walker, among which we may mention the single stroke bell and compound key (1851); a galvanometer-semaphore (1854); a single wire electro-magnetic telegraph semaphore (1863); and various contrivances for putting passengers and guards in electrical communication with each other, some of which are as recent as 1875.

Many years before, associating himself with the erection and maintenance of telegraphs, Mr. Walker had taken an active part in the proceedings of the London Electrical Society, so much so that in 1843 he became its secretary. Prior to the formation of the *Electrical Magazine* in that year, however, Mr. Walker had shown his taste for literary work by the publication of a manual of electrotyping which has since, we believe, run through as many editions as any of our most popular novels. Mr. Walker's name was also associated with Dr. Lardner's in the literary scheme for popularising scientific subjects. In the year 1853 De La Rive's celebrated "Treatise on Electricity in Theory and Practice" was introduced to English readers by a translation of Mr. Walker's, and soon after its appearance, namely, in 1855, he was elected a Fellow of the Royal Society.

Digitized by Google

Several original papers from the same pen appear in the *Proceedings* of the Royal Society and *Phil. Trans.* between the year just named and 1862, chiefly relating to magnetic storm phenomena and meteorology—subjects in which the deceased gentleman always took the greatest interest. In this connection it may be mentioned that the situation of the lines over which he had control brought him into relation with the chiefs of the Greenwich Observatory, and on all occasions he was ready to render them the greatest assistance in the matter of earth currents, magnetic storms, and the telegraphing of Greenwich time signals. Indeed, the first introduction of these latter seems to have originated with Mr. Walker and the late Astronomer-Royal, Sir G. B. Airy, some thirty years ago.

With the objects and formation of the Society of Telegraph Engineers Mr. Walker took a lively interest for many years, and in 1876 was elected its president. The address which he delivered on that occasion was published at length in the *Journal* of the Society, and will well repay perusal even now. Mr. Walker attained the full age allotted to man, having died in his 71st year.

CORRESPONDENCE.

STATIC ELECTRICITY AND QUANTITY.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In reply to Mr. Sprague's letter on page 186, I will first remark on his statements about quantity of force, as I am in hopes that it may lead to a comprehension on my part of what Mr. Sprague means by the word quantity, for it certainly appears to me at present that he does not use the term in its ordinary sense.

Newton says, Definition IV., "Vis impressa est actio in corpus exercita, ad mutandum ejus statum vel quiescendi vel movendi uniformiter in directum." This definition does not imply that force is something having a separate existence, and this was very clearly put by the late Professor Clifford when he described force as the change of momentum of a body considered as depending upon its position relative to other bodies. Now, it is convenient to be able to express this idea in a single word in place of always using a long expression, and hence the utility of the word force. Having, however, once introduced the word, we see that it is something which has both magnitude and direction, and therefore we say that a force is a quantity having direction.

I made use of the idea of force merely to point out that the idea of magnitude, or quantity, may be associated with what is admittedly not a thing having a separate existence of its own, but I do not, therefore, either affirm or deny that electricity has such a separate existence, as we are as yet entirely ignorant of its nature.

Now, Faraday's ice-pail experiments show that two or more electrifications can be combined experimentally with a result of the same kind as when two quantities are added algebraically. "We are, therefore," says Maxwell, "entitled to use language fitted to deal with electrification as a quantity as well as a quality, and to speak of any electrified body as charged with a certain quantity of positive or negative electricity." Maxwell, at the same time, cautions us against too hastily placing electricity in any known category of physical quantities, since all that the ice-pail experiments prove is that electricity cannot be created or annihilated, so that, if the total quantity of electricity within a closed surface be altered, the increase or diminution must have passed through the surface.

One expression of Mr. Sprague's is completely incomprehensible to me, viz., that in which he says that attraction and pressure "cannot be expressed as quantities but as degrees."

By a quantity is meant something which can be either greater or less or equal to something else of a similar kind. What else does Mr. Sprague mean when he speaks of degrees?

It appears from Mr. Sprague's letter that I have misunderstood him in supposing him to hold that electricity is a form of energy, but as he denies this I am unable to understand the table which he gives on page 129 of this volume. Mr. Sprague's statement on page 151 of Vol. IV., "I hold that electricity has no actual existence, that it is not an element, nor a fluid; that it is not a force, but that it is like heat, simple energy—energy distributed upon chains of material molecules," &c., also seems to me quite irreconcileable with his present statement that he does not hold electricity to be a form of energy. With the latter statement before me I should have refrained from the above quotation, supposing simply that Mr. Sprague had changed his opinion, had it not appeared to me practically identical with the statement made in the table which I have alluded to.

Mr. Sprague now says that he considers electricity to be the square root of energy.

Now, quantity of electricity Q, is of the dimensions $L^{\frac{3}{2}} M^{\frac{1}{2}} T^{-1}$ in the electrostatic system, and $L^{\frac{1}{2}} M^{\frac{1}{2}}$ in the electromagnetic system, L, M, T, representing the units of length, mass, and time respectively; again, electromotive force E, is of the dimensions $L^{\frac{1}{2}} M^{\frac{1}{2}} T^{-1}$ in the electrostatic system, and $L^{\frac{3}{2}} M^{\frac{1}{2}} T^{-2}$ in the electro-magnetic. But, as I pointed out in my letter on page 162, E Q is an expression for energy, and therefore if Q^2 were also an expression of energy, as Mr. Sprague asserts, it would be necessary that E and Q should be of equal dimensions in the fundamental units, which, however, is not the case.—Yours, &c.,

G. W. von TUNZELMANN.

THE ACTION OF MICROPHONES.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I am sorry I have not been able to reply to your other correspondents at an earlier date on account of pressure of business, but will now take advantage of your kindness.

In reference to "Loose Contact's" letter in your issue of December 23, in his desire to indulge in invective I am afraid he has run away with himself, and asserts that I am wrong, but fails to point where, no doubt an oversight, or his failing to see the argument is possibly my fault through want of lucidity in writing, which I will now endeavour to make clear.

With a platinum and carbon contact an increase of current takes place in the primary circuit on a pressure greater than the normal being applied to the diaphragm. The resistance of the circuit being diminished, a corresponding diminution of current takes place when the pressure is removed.

This current wave will cause induced currents to flow in the transmitter secondary, which simple fact is I think well enough known. Therefore, microphonic action will take place independent of an intermittent contact with or without matter filling the gaps.

With this in view it is clear it is not necessary that an open contact should exist to produce microphonic action, *i.e.*, induced currents in the secondary through variation of current in the primary, and by the experiment I endeavoured to show that a single thrust and recovery given to the diaphragm produces this effect, with which it was impossible any open contact could exist. All that remains, then, is to consider whether an intermittent contact can possibly exist. One little circumstance I omitted to mention in my last letter, and to which I would direct Mr. Rathbone's attention, is that if the carbon be drawn away from the diaphragm the platinum stud *will follow* the carbon button through the space of a quarter of an inch or more before it breaks circuit. This is a small matter, but its importance is obvious, and the effect of this action being prevented by the platinum stud sticking to the diaphragm by rust is I presume perfectly well known to "Loose Contact," who, I have no doubt (judging from the tone of his letter), has a practical acquaintance with the instrument. In consideration of the above and the parti-

Digitized by Google

culars of the construction of this transmitter given in my last, I hold that the existence of an intermittent contact is a mechanical impossibility when spoken into in a colloquial tone. All sound waves striking the diaphragm force it inwards, thereby increasing the normal pressure.

Regarding his suggested experiment with a metallic body supplanting the carbon, I would feel inclined to ask if "Loose Contact" has tried it? I have, and, after *very careful* adjustment of the transmitter, got it to speak, but that was all. It was of the faintest possible description, and might be safely considered a practical failure, the trial being made under precisely similar conditions. I enclose the brass button for your inspection.

Now, according to "Loose Contact's" letter, I should have precisely the same result as if carbon had been employed. How was it different? Unless from the fact that the carbon possesses a property which is foreign to the brass. Perhaps he can explain.

Further, I connected it up with the "bridge," and found the resistance to be ·9 ohm (with the carbon it was 4·8 ohms), and "tickled" it with a bristle, but the needle of the galvanometer did not respond, as when the carbon was used. How is this to be explained? Would it not be fair to assume that the brass had reached its maximum conductivity?

These results are disappointing after reading "Loose Contact's" letter.

The carbon spoke as only carbon can, and if "Loose Contact" has any other substance, compound or elementary, that will do the work as well, I will be very happy to give it a trial.

I would here take the liberty of reminding "Loose Contact" that contradictory assertion without proof is of little value in a discussion of this nature, and that seeing my letter, which you have kindly given space to, bears my signature, I think "Loose Contact," in common courtesy, should also sign his name, and until such time as he finds it convenient to do so I must decline to take further notice of his contributions.

In the same issue I observe a letter from Mr. Berliner, in which he suggests an air film as the cause of microphonic action. In the case of the platinum point bearing against the carbon, I can hardly conceive two *bodies in contact*, and a *third one between them*. I think the admission of a possible air space would be extremely favourable to the "arc" theory. Would not Mr. Berliner think the diminution of resistance of the transmitter in vacuo to be due to the extraction of air from the pores of the carbon itself, rather than to the exhaustion of the surrounding atmosphere, the rounded platinum point being *in contact* with the carbon, which it decidedly is when properly adjusted. The effect I fancy is somewhat akin to that which takes place in a vacuum tube.—Yours, &c.,

R. D. SMILLIE, Electrician.

National Telephone Company (Limited), Glasgow.

January 10, 1883.

"GLOW" LAMPS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I have to thank Mr. Preece for calling my attention to the definition of "glow" given in the "Imperial Dictionary." It is, "to shine with intense heat, or, perhaps more correctly, to shine with a white heat, to exhibit incandescence, hence, in a more general sense, to shine with a bright lustre." Mr. Preece then asks if this is not exactly applicable to the carbon filament in a Swan lamp when heated by the current. I frankly admit that it is; but then it is also applicable to much more. It is equally applicable to the arc lamp, and will even take in a gas flame. My objection to the term "glow" is that it has too wide a meaning in the English language. The German verb *glühen* has, I believe, a more restricted sense, and, primarily, means to make red hot. But our word glow has come to have a most elastic signification, far more elastic even than the above dictionary definition. In the general sense of the people, and this after all is the truest test, it means, on the one hand, a luminous effect *similar* to that given by incandescence but not necessarily due to incandescence, and on the other a sensation like that due to warmth. The same dictionary speaks of a face "glowing" with blushes, a person glowing with animation, and so on. A word which includes the spark of a glowworm, or the gleam of a firefly, the reflection of sunlight on snow, the intense lustre of the voltaic arc, and a feeling of warmth, is surely discredited as a distinctive term for the incandescence lamp. What, for example, should we do if another electric lamp were invented which "glowed" equally well by some other means than incandescence?

It is, of course, much easier to find fault than to do better. But I think the lamp should be named, not from its *appearance*, but from some essential property or peculiar feature of its action. If "incandescence" is too long (and though longish it is really not difficult to pronounce and not ineuphonious) we have the term "filament" lamp, and a still shorter term would be "loop" lamp. Incandescence might remain the generic name.—Yours, &c.,

J. MUNRO.

MR. ELLIS LEVER'S PREMIUM FOR MINING LAMPS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Can you or any of your readers kindly give me particulars (or state where they may be obtained) of requirements of the mining lamps for which Ellis Lever, Esq., M.P., has offered a premium of £250?—Yours, &c.,

INVENTOR.

CANTOR LECTURES.*

DYNAMO-ELECTRIC MACHINERY.

BY PROFESSOR SILVANUS P. THOMPSON, B.A., D.SC., M.S.T.E.

Lecture I. (concluded)—The Dynamo in Theory.

(CONTINUED FROM PAGE 190.)

Field-magnets.

The coils of the field-magnets of a dynamo cannot be constructed of no resistance. They, therefore, always waste some of the energy of the currents in heat. It has, therefore, been argued that it cannot be economical to use electro-magnets in comparison with permanent magnets of steel, which have only to be magnetised once for all. Nevertheless, there are certain considerations which tell in favour of electro-magnets. For equal power, their prime cost is less than that of steel magnets, which, moreover, are not permanent, but require remagnetising at intervals. Moreover, as we have seen, from the fact that there is a limiting velocity at which it is safe to run a machine, it is important, in order not to have machines of needlessly great size, to use the most powerful field-magnets possible. But if we do not get our magnetism for nothing, and find it more convenient to spend part of our current upon the electro-magnets, economy dictates that we should so construct them that their magnetism may cost us as little as possible. To magnetise a piece of iron requires the expenditure of energy; but when once it is magnetised, it requires no further expenditure of energy (save the slight loss by heating in the coils, which may be reduced by making the resistance of the coils as little as possible) to keep it so magnetised, provided the magnet is doing no work. Even if it be doing no work, if the current flowing round it be not steady, there will be loss. If it do work, say, in attracting a piece of iron to it, then there is an immediate and corresponding call upon the strength of the current in the coils, to provide the needful energy. This point may be illustrated by the following experiment:—Let a current from a steady source (see Fig. 10) pass through an incandescent lamp, and also through an electro-magnet, whose cores it magnetises. When once established, the current is perfectly steady, and none of its energy is wasted on the magnet (save the negligible trifle due to the resistance of the coils). But if now the magnet is allowed to do work in attracting an iron bar toward itself, the light of the lamp is seen momentarily to fade. When the iron bar is snatched away, the light exhibits a momentary increase; in each case resuming its original intensity when the motion ceases. Now, in a dynamo where, in many cases, there

* Reprinted from the *Journal of the Society of Arts*.

Digitized by Google

are revolving parts containing iron, it is of importance that the approach of a recession of the iron parts should not produce such reactions as these in the magnetism of the magnet. Large, slow-acting field-magnets are therefore advisable. The following points embody the conditions for attaining the end desired.

(*a.*) The body of the field-magnets should be solid. Even in the iron itself currents are induced, and circulate round and round whenever the strength of the magnetism is altered. These self-induced currents tend to retard all changes in the degree of magnetisation. They are stronger in proportion to the square of the diameter of the magnet, if cylindrical, or to its area of cross-section. A thick magnet will, therefore, be a slow-acting one, and will steady the current induced in its field.

(*b.*) Use magnets having in them plenty of iron. It is important to have a sufficient mass, that saturation may not be too soon attained.

(*c.*) Use the softest possible iron for field-magnets, not because soft iron magnetises and demagnetises quicker than other iron (that is here no advantage); but because soft iron has a higher magnetic susceptibility than other iron—is not so soon saturated.

(*d.*) Use long magnets. Again, the use of long magnets is to steady the magnetism, and, therefore, to steady the current. A long magnet takes a longer time than a short magnet to magnetise and demagnetise. It costs more than a short magnet, it is true, and requires more copper wire in the exterior coil; but the copper wire may be made thicker in proportion, and will offer less resistance. The magnetism so obtained should be utilised as directly as possible, therefore

(*e.*) Place the field-magnets or their pole-pieces as close to the rotating armature as is compatible with safety in running.

(*f.*) Avoid edges and corners on the magnets and pole-pieces if you want a uniform field. The laws of distribution of the mag-

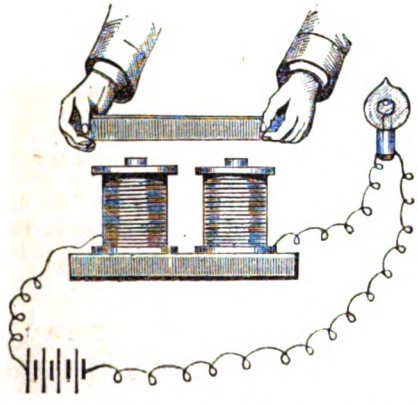

FIG. 10.—Reaction of Moving Mass of Iron on an Electro-Magnet.

netic lines of force round a pole are strikingly akin to those of the distribution of electrification over a conductor. We avoid edges and points in the latter case, and ought to do in the former. If the field-magnets or their pole-pieces have sharp edges, the field cannot be uniform, and some of the lines of force will run uselessly through the space outside the armature instead of going through it. Theoretically, the very best form to give externally to a magnet is that of the curves of the magnetic lines of force.

(*g.*) Reinforce the magnetic field by placing iron, or, better still, electro-magnets, within the rotating armature. In many cases this is done by giving the armature coils iron cores which rotate with them; in other cases, the iron cores of internal masses are stationary. In the former case there is loss by heating; in the latter, there are structural difficulties to be overcome. Siemens has employed a stationary mass within his rotating drum-armature. Internal electro-magnets serving the function of concentrating the magnetism of the field, and of so providing a continuous magnetic circuit, have been used by Lord Elphinstone and Mr. Vincent. A similar device obtains in Sir W. Thomson's "mouse-mill" dynamo, and in Jürgensen's dynamo.

(*h.*) In cases where a uniform magnetic field is not desired, but where, as in dynamos of the second class, the field must have varying intensity at different points, it may be advisable specially to use field-magnets with edges or points, so as to concentrate the field at certain regions.

Pole-pieces.

(*i.*) The pole-pieces should be heavy, with plenty of iron in them, for reasons similar to those urged above.

(*j.*) The pole-pieces should be of shapes really adapted to their functions. If intended to form a single approximately uniform field, they should not extend too far on each side. The distribution of the electromotive force in the various sections of the coils on the armature depends very greatly on the shape of the pole-pieces.

(*k.*) Pole-pieces should be constructed so as to avoid, if possible, the generation in them of useless Foucault currents. The only way of diminishing loss from this source is to construct them of laminæ, built up so that the mass of iron is divided by planes in a direction perpendicular to the direction of the currents, or of the electromotive forces tending to start such currents.

(*l.*) If the bed-plates of dynamos are of cast iron, care should be taken that these bed-plates do not short-circuit the magnetic lines of force from pole to pole of the field-magnets. Masses of brass, zinc, or other non-magnetic metal may be interposed; but are at best a poor resource. In a well-designed dynamo there should be no need of such devices.

Field-magnet Coils.

(*m.*) In order to be of the greatest possible service, the coils of the field-magnets should be wound on most thickly at the middle of the magnet, not distributed uniformly along its length, nor yet crowded about its poles. The reason for this is two-fold. Inspection of Fig. 6 will show that many of the lines of force of a magnet "leak out" from the sides of the magnet before reaching its poles, where they should all emerge if the mass of the magnet were perfectly equally magnetised throughout its whole length. Internally, the magnetisation of the magnet is greatest at its centre. At, or near the centre, therefore, place the magetising coils, that the lines of force due to them may run through as much iron as possible. The second reason for not placing the coils at the end is this—any external influence which may disturb the magnetism of a magnet, or affect the distribution of its lines of force, affects the lines of force in the neighbourhood of the pole far more than those in any other region. It is for this reason that in Bell's telephones, where it is desired to make a magnet most sensitive to variations in intensity, the coils are fixed on at the pole. In the field-magnet of a dynamo, on the contrary, where the magnet is wanted to be as steady and as constant as possible in its magnetic power, the coils should not be placed on the poles.

(*n*) The proper resistances to give to the field-magnet coils of dynamos have been calculated by Sir William Thomson,* who has given the following results:—

For "Series Dynamo," make the resistance of the field-magnets a little less than that of the armature. Both of them should be small, compared with the resistance of the external circuit. The ratio of the waste by heating in the machine, to the total electric work of the machine, will be—

$$\frac{\text{waste}}{\text{total work}} = \frac{R_M + R_A}{R_M + R_A + R_X}$$

$$\text{and } \frac{\text{useful work}}{\text{total work}} = \frac{R_X}{R_M + R_A + R_X}$$

where R_M is the resistance of the magnets,

R_A „ „ of the armature,

R_X „ „ of the external circuit.

For a "Shunt Dynamo," the rule is different. The best proportions are when such that

$$R_X = \sqrt{R_M R_A} \text{ or that}$$

$$R_M = \frac{R_X^2}{R_A}$$

also the ratio of useful work is:—

$$\frac{\text{useful work}}{\text{total work}} = \frac{1}{1 + 2\sqrt{\frac{R_A}{R_M}}}$$

An example of the latter may be of advantage. Suppose it was wished that the waste should not be more than 10 per cent. of the useful work, the ratio of the formula must equal $\frac{10}{11}$, or $1 \div 1\frac{1}{10}$. Hence $\sqrt{\frac{R_A}{R_M}}$ must equal $\frac{1}{20}$; or R_M the resistance of the field-magnets must be 400 times R_A that of the armature.

Armature Cores.

(*o*) Theory dictates that if iron is employed in armatures, it must be slit or laminated, so as to prevent the generation o

* British Association Report, 1881, p. 528.

Digitized by Google

Foucault currents. Such iron cores should be structurally divided in planes normal to the circuits round which electromotive force is induced; or should be divided in planes parallel to the lines of force and to the direction of the motion. Cores built up of varnished iron wire, or of thin discs of sheet iron separated by varnish, asbestos paper, or mica, partially realise the required condition.

(*p.*) Armature cores should be so arranged that the direction of polarity of their magnetisation is never abruptly reversed during their rotation. If this precaution is neglected the cores will be heated.

Armature Coils.

(*q.*) All needless resistance should be avoided in armature coils, as hurtful to the efficiency of the machine. The wires should, therefore, be as short and as thick as is consistent with obtaining the requisite electromotive force, without requiring an undue speed of driving.

(*r.*) The wire should be of the very best electric conductivity. The conductivity of good copper is so nearly equal to that of silver (over 96 per cent.), that it is not worth while to use silver wires in the armature coils of dynamos.

(*s.*) In cases where rods or strips of copper are used instead of mere wires, care must be taken to avoid Foucault currents by laminating such conductors, or slitting them in planes parallel to the electromotive force, that is to say, in planes perpendicular to the lines of force, and to the direction of the rotation.*

(*t.*) In dynamos of the first class, when used to generate currents in one direction, since the currents generated in the coils are doing half their motion inverse to those generated during the other half of their motion, a commutator or a collector of some kind must be used. In any single coil without a commutator, the alternate currents would be generated in successive revolutions, if the coil were destitute of self-induction currents, whose variations may be graphically expressed by a recurring sinusoidal

Fig. 11.

curve, such as Fig. 11. But if by the addition of a simple split-tube commutator the alternate halves of these currents are reversed, so as to rectify their direction through the rest of the circuit, the resultant currents will not be continuous, but will be of one sign only, as shown in Fig. 12, there being two currents

Fig. 12.

generated during each revolution of the coil. If two coils are used, at right-angles to each others' planes, so that one comes into the position of best action, while the other is in the position of least action (one being normal to the lines of force, when the other is parallel to them), and their actions be superposed, the result will be, as shown in Fig. 13, to give a current

Fig. 13.

which is continuous, but not steady, having four slight undulations per revolution. If any number of separate coils are used, and their effects, occurring at regular intervals, be superposed, a similar curve will be obtained, but with summits proportionately more numerous and less elevated. When the number of coils used is very great, and the overlappings of the curves still more complete, the row of summits will form practically a straight line, or the whole current will be practically constant.

(*u.*) The rotating armature coils ought, therefore, to be divided into a large number of sections, each coming in regular succession into the position of best action.

(*v.*) If these sections or coils are independent of each other, each coil, or diametral pair of coils, must have its own commutator. If they are not independent, but are wound on in continuous connection all round the armature, a collector is needed, consisting of parallel metallic bars as numerous as the sections, each bar communicating with the end of one section and the beginning of the next.

(*w.*) In any case, the connections of such sections and of the commutators, or collectors, should be symmetrical round the axis; for if not symmetrical, the induction will be unequal in the parts that successively occupy the same positions with respect to the field-magnets, giving rise to inequalities in the electromotive force, sparking at the commutator, or collector, and other irregularities.

(*x.*) In the case where the coils are working in series, it is advantageous to arrange the commutator to cut out the coil that is in the position of least action, as the circuit is thereby relieved of the resistance of an idle coil. But no such coil should be short-circuited to cut it out. In the case where the coils are working in parallel, cutting out an idle coil increases the resistance, but may be advisable to prevent heating from waste currents traversing it from the active coils.

(*y.*) In the case of pole-armatures, the coils should be wound on the poles rather than on the middles of the projecting cores; since the variations in the induced magnetism are most effective at or near the poles. (See § *m.*)

(*z.*) Since it is impossible to reduce the resistance of the armature coils to zero, it is impossible to prevent heat being developed in those coils during their rotation; hence it is advisable that the coils should be wound with air spaces in some way between them, that they may be cooled by ventilation.

(*aa.*) The insulation of the armature coils should be ensured with particular care, and should be carried out as far as possible with mica and asbestos, or other materials not liable to be melted, if the armature coils become heated.

Commutators, Collectors, and Brushes.

(*ab.*) Commutators and collectors being liable to be heated through imperfect contact, and liable to be corroded by sparking, should be made of very substantial pieces of copper.

(*ac.*) In the case of a collector made of parallel bars of copper, ranged upon the periphery of a cylinder, the separate bars should be capable of being removable singly, to admit of repairs and examination.

(*ad.*) The brushes should touch the commutator or the collector at the two points, the potentials of which are respectively the highest and the lowest of all the circumference. In a properly and symmetrically built dynamo, these points will be at opposite ends of a diameter.

(*ae.*) In consequence of the armature itself, when traversed by the currents, acting as a magnet, the magnetic lines of force of the field will not run straight across, from pole to pole, of the field-magnets, but will take, on the whole, an angular position, being twisted a considerable number of degrees in the direction of the rotation. Hence the diameter of commutation (which is at right angles to the resultant lines of force in machines of the Siemens and Gramme type, and parallel to the resultant lines of force in machines of the Brush type) will be shifted forward. In other words, the brushes will have a certain angular lead. The amount of this lead depends upon the relation between the intensity of the magnetic field and the strength of the current in the armature. This relation varies in the four different types of field-magnets. In the series dynamo, where the one depends directly on the other, the angle of lead is nearly constant, whatever the external resistance. In other forms of dynamo the lead will not be the same, because the variations of resistance in the external circuit do not produce a proportionate variation between the two variables which determine the angle of lead.

(*af.*) Hence in all dynamos it is advisable to have an adjustment, enabling the brushes to be rotated round the commutator or collector, to the position of the diameter of commutation for the time being. Otherwise there will be sparking at the brushes, and in part of the coils at least the current will be wasting itself by running against an opposing electromotive force.

(*ag.*) The arrangements of the collector, or commutator, should be such that, as the brushes slip from one part to the next, no coil or section in which there is an electromotive force should be short circuited, otherwise work will be lost in heating that coil. For this reason, it is well so to arrange the pole pieces that the several sections or coils on either side of the neutral position should differ but very slightly in potential from one another.

(*ah.*) The number of contact points between the brushes and the collector, or commutator, should be as numerous as possible, for by increasing the number of contacts, the energy wasted in sparks will be diminished inversely as the square of that number. The brushes might, with advantage, be laminated, or made of parallel loose strips of copper, each bearing edgeways on the collector.

Relation of Size to Efficiency.

The efficiency of a dynamo-electric machine is the ratio of the

*It will be observed that the rule for eliminating Foucault currents is different in the three cases, for magnets and their pole-pieces, for moving iron armature cores, and for moving conductors in the armature.

Digitized by Google

useful electrical work done by the machine to the total mechanical work applied in driving it. Every circumstance which contributes to wasting the energy of the current reduces the efficiency of the machine. In the preceding paragraphs it has been shown what the chief electric sources of waste are, and how they may be avoided. The precautions needful to obviate Foucault currents, to avoid reversals of magnetisation, to get rid of needless resistance, to obviate opposing electromotive forces, have been detailed. Mechanical friction of the moving parts can be minimised also by due mechanical arrangements. But one thing cannot be entirely obviated, because even the best conductors employed have a certain resistance. We cannot prevent the heating of the conducting coils; and the more powerful the current generated by the machine the more important does this source of waste become. There is but one way to reduce this, and that is by increasing the size of the machines. For some three years or so I have been the advocate of large dynamo machines, not because I have any admiration for mere bigness, but because, as in steam-engines so in dynamos, the larger machines may be made more efficient than the small, in proportion to their cost. In discussing the relation of size to efficiency, I shall assume, for the sake of argument, that the size of any machine can be increased n times in every dimension, and that though the dimensions are increased, the velocity of rotation remains the same, and that the intensity of the magnetic field, per square centimetre, remains also constant. If the linear dimensions be n times as great in the larger machine as in the smaller, the area it stands on will be increased n^2 times, and its volume and weight n^3 times. The cost will be less than n^3 times but greater than n times. If the same increase of dimensions in the coils be observed (the number of layers and of turns remaining the same as before), there will be in the armature coils a length n times as great, and the area of cross-section of the wire will be n^2 times as great as before. The resistance of these coils will, therefore, be but $\frac{1}{n}$ part of the original resistance of the smaller machine. If the field-magnet coils are increased similarly they will offer only $\frac{1}{n}$ of the resistance of those of the smaller machine. Moreover, seeing that while the speed of the machine is the same, the area cut through by the rotating coils is increased n^2 times, these coils will in the same time cut n^2 times as many lines of force, or the electromotive force will be increased n^2 times. Supposing the whole of the circuit to be similarly magnified, its resistance will also be but $\frac{1}{n}$ of the previous value.

If the machine is a "series"-wound dynamo, an electromotive force n^2, working through $\frac{1}{n}$ resistance, will give a current n^3 times as great as before. Such a current will, as a matter of fact, much more than suffice to bring up the magnetic field to the required strength, viz., n^2 times the area of surface magnetised to the same average intensity per square centimetre, as stipulated; for the mass of iron being n^3 times as great, it need not be so much saturated as before to give the required field. Here an economy may be effected, therefore, by further reducing the number of coils, and, therefore, the wasteful resistance of the field magnet coils, in the proportion of n^3 to n^2, or to $\frac{1}{n}$ of its already diminished value. Even if this were not done, by the formula given above for the electrical efficiency of a "series" dynamo, the waste, when working through a constant external resistance, will be n-fold less than with the smaller machine. Now, if the current be increased n^3 times, and the electromotive force n^2 times, the total electric work which is the product of these will be n^5 times greater than in the small machine, and it will consume n^5 times as much power to drive it.* It is clearly an important economy, if a machine costing less than n^3 times as much, will do n^5 as much work (to say nothing of the increased ratio of efficiency). A machine doubled in all its linear dimensions will not cost eight times as much, and will be electrically thirty-two times as powerful a machine.

Suppose the machine to be "shunt" wound, then to produce the field of force of n^2 times as many square centimetres area, will require (if the electromotive force be n^2 times as great) that the absolute strength of the current remain the same as before in the field-magnet coils. This can be done by using the same sized wire as before, and increasing its length n^2 times, to allow for n times as many turns, of n times as great a diameter each, in the same number of layers of coils as before. In this case the work done in the shunt being equal to the product of the n^2-fold electromotive force into the unaltered current will be only n^2 times as great, while the whole work of the machine is augmented n^5 times. Now, if while augmenting the total work n^5 times, we have increased the waste work not to n^5 times, but only n^2 times, it is clear that the ratio of waste to the total effect is diminished n^3-fold. There is, therefore, every reason to construct large machines, from the advantage of economy, both in relative prime cost and relative efficiency.

Being desirous of testing the correctness of the deduction that the working capacity of a machine of n-fold linear dimensions is n^5 times as great, I constructed a little instrument, of which a drawing is given in Fig. 14. In this instrument there are two

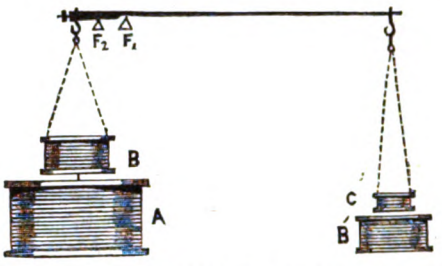

FIG. 14.—S. P. Thompson's Experimental Balance.

pairs of coils, that on the left being in every way the counterpart of that on the right, but of double linear dimensions. When all four coils were traversed by the same current, the point of equilibrium was $\frac{1}{17}$ of the length of the beam from the extremity; or the attraction of the larger system was sixteen times that of the smaller. Now, it is clear that the larger force can be exerted through double the distance, or that the work-power is 32-fold, and 32 is 2^5, as theory requires. After I had constructed my apparatus I learned that M. Marcel Deprez had made a very similar arrangement, but without the beam, to prove that the statical forces of similar machines are (see foot-note *ante*) proportional to the fourth power of the linear dimensions. M. Deprez's instrument consisted of a modified Mascart's electro-dynamometer, having a coil suspended from a balance, and acted upon by two others, placed axially above and below it (see Fig. 15). The force was measured by directly balancing it against weights. Two such arrangements were made, one double the size of the other, and when equal currents were sent through them M. Deprez found the forces to be as 5·600 to 0·355 kilos., or almost exactly 16 to 1.

Methods of Exciting the Field Magnetism.

It only remains to develop certain theoretical considerations respecting the method of exciting the magnetism of the field, in which the armatures are to revolve. The four main methods have already been alluded to at the outset of this lecture; but nothing has been said about the advantages or disadvantages of the four systems.

Magneto-Dynamos.—The magneto-dynamos (Fig. 4) have the

---

* This calculation agrees with the result deduced on entirely different principles by M. Marcel Deprez. M. Deprez considers the mutual reaction, dF, between two elements, ds and ds', of a system of conductors which, by Ampère's principle, is

$$dF = C^2 \frac{ds\, ds'}{r^2} f(a),$$

where C is the current, r the distance of the elements apart, and $f(a)$ a certain function of the machine, independent of its size. Writing a' for the area, we have

$$dF = \frac{C^2}{a^2} \cdot \frac{ads \cdot ads'}{r^2} \cdot f(a)$$
$$= \frac{C^2}{a^2} \cdot \frac{dv \cdot dv'}{r^2} \cdot f(a),$$

which, if the linear dimensions be increased n times, becomes

$$dF' = \frac{C^2}{a^2} \cdot \frac{n^3 dv \cdot n^3 dv'}{n^2 r^2} \cdot f(a)$$
$$= n^4 dF,$$

whence, since this is true for all elements of the circuits, $\frac{F'}{F} = n^4$, which is Deprez's so-called "law of similars," which asserts that for similar machines the "statical effort" increases as the fourth power of the linear dimensions. But work W = F × distance, and, in the similar machine whose dimensions are increased n times, the available distance through which the force F′ can act is also n times greater. Hence, $\frac{W'}{W} = n^5$, as above.

Digitized by Google

advantage, in theory at least, that their electromotive force is very nearly exactly proportional to the velocity of rotation; though, of course, the variable difference of potential between the terminals of the circuit will depend on the relation of the resistance of the external circuit to the internal resistance of the armature coils. They possess the disadvantage that, since steel cannot be permanently magnetised to the same degree as that which soft iron can temporarily attain, they are not so powerful as other dynamos of equal size.

Separately-excited Dynamos.—The separately-excited dynamo (Fig. 3) has the same advantage as the magneto-machine, in electromotive force being independent of its accidental changes of resistance in the working circuit, but is more powerful. It has, moreover, the further advantage that the strength of the field is under control. For by varying either the electromotive force or the resistance in the exciting circuit, the strength of the magnetic field is varied at will. It has the disadvantage of requiring a separate exciting machine.

Series Dynamos.—The ordinary, or series dynamo (Fig. 1), is usually a cheaper machine, for equal power, than any of the other forms, as its coils are simpler to make than those of a shunt machine, and it wants no auxiliary exciter. It has the disadvantages of not starting action until a certain speed has been attained, or unless the resistance of the circuit is below a certain minimum. It is also liable to become reversed in polarity, a serious disadvantage when this machine is applied for electroplating, or for charging accumulators.

From its arrangements, it is clear that any increase of resistance in the circuit lessens its power by diminishing the strength of its magnetic field. Hence it is better adapted for use with lamps arranged in parallel arc than for lamps arranged in series.

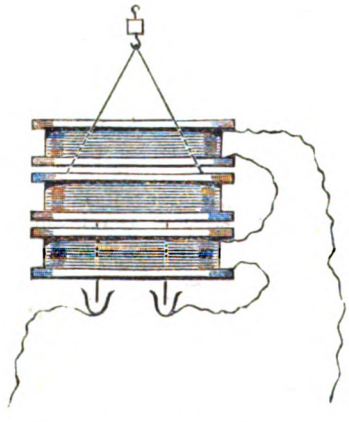

FIG. 15.—Marcel Deprez's Electro-dynamic Balance.

An additional lamp switched in, in series, adds to the resistance of the circuit, and diminishes the power of the machine to supply current. While, on the other hand, an additional lamp in parallel reduces the total resistance offered by the network of the circuit, and adds to the power of the machine to provide the needed current. It is easy to regulate the currents given by a series dynamo, by introducing a shunt of variable resistance across the field-magnet, thus altering the magnetising influence of the current.

Shunt Dynamos.—The shunt dynamo (Fig. 2), has several advantages over other forms. It is less liable to reverse its polarity than the series dynamo, and it is commonly considered as providing the magnetising power to the magnets with less waste of current. Moreover, for a set of lamps in series, its power to supply the needful current increases with the demands of the circuit, since any added resistance sends additional current round the shunt in which the field-magnets are placed, and so makes the magnetic field more intense. On the other hand, there is a greater sensitiveness to inequalities of driving in consequence of the great self-induction in the shunt. As previously pointed out, when there are sudden changes in the electromotive force acting in a complex circuit, the momentary currents thus set up do not distribute themselves in the various parts of the circuit in the simple inverse ratio of the resistances, for their distribution depends also, and in some cases chiefly, upon the self-induction in the various parts. It is more difficult to set up a sudden current in a circuit whose self-induction is great (or which, for example, consists of many turns wound closely together, so that they exercise great inductive action on each other, especially if they be wound about an iron core) than in one in which the self-induction is small. We cannot here follow further the mathematical law of the action of self-induction on momentary changes of electromotive force. But the application to the shunt-wound dynamo is too important to be passed over.

Any of these systems may be applied either in direct current or in alternate current machines. Each of these four systems of exciting the field magnetism has its own merits for special cases, but none of them is perfect. Not one of these methods will insure that, with a uniform speed of driving, either the electromotive force or the current shall be constant, however the resistances of the circuit are altered.

But, though theory tells us that none of these systems is perfect, theory does not leave us without a guide. Thanks to the genius of M. Marcel Deprez, we have been taught how to combine these methods so as to secure in practice a machine which shall, when driven at a constant speed, give either a constant electromotive force or a constant resistance. A consideration of the various methods of combining the four systems of exciting the field-magnetism is reserved for the lecture on the dynamo in practice.

Meantime, it may safely be said that there is no such thing yet as a best dynamo. As with the different kinds of voltaic batteries, some of which are used for telegraph work, others for electric bells, and others for blasting, so is it also with dynamos. One form is best for one purpose and another for another. One gives steadier currents, another is less liable to heat, a third is more compact, a fourth is cheaper, a fifth is less likely to reverse its currents, a sixth gives a greater volume of current, while a seventh evokes a higher electromotive force. Indeed, in the present transitional state of our knowledge with respect to dynamo-electric machinery, it is safe to assert that, for a long time to come, there will be no finality attained to. As with the steam-engine, however, so with the dynamo-machine, there will probably be a constant and progressive evolution, finally settling down upon two or three typical forms, which will survive the innumerable comparatively crude machines which, as yet, have taken shape, and come into active service.

(TO BE CONTINUED.)

DETECTION OF METALLIC MASSES IN THE HUMAN BODY.*

BY ALEXANDER GRAHAM BELL.

(CONCLUDED FROM PAGE 192.)

Experiments Continued in Boston.

Mr. Tainter forwarded from Washington drawings of an improved apparatus he had designed to remedy the defects of the instrument shown in Fig. 18, in which the case, adjusting screws, &c., were all to be composed of ebonite.

Mr. Gleason constructed for me a number of such ebonite instruments differing slightly from one another in detail, and the apparatus shown in Fig. 20 combined the different points that had been approved.

The two coils A B were eccentrically arranged in two circular discs of ebonite, C D, and the adjustment was obtained by means of an ebonite key, O, like the key used for tuning pianos, which turned a cam, M, pivoted in the upper disc and working in a slot, N, in the lower disc.

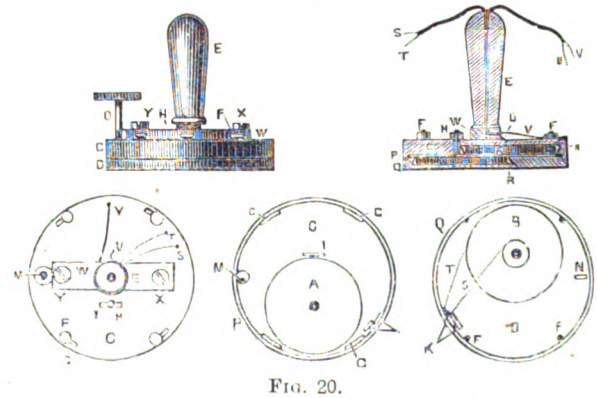

FIG. 20.

In order to prevent any movement of the coils, excepting that produced by the adjusting key O, each coil was placed in a recess turned out in its ebonite disc, the edges of which were bevelled as shown at R. Paraffin was then poured in so as to fill up each recess. But this alone did not prevent a slight pulsation of sound when the instrument was swayed from side to side, and a very slight pressure of the finger on the thin portion of the ebonite plate under the coil B was sufficient to destroy the balance.

This was remedied by strengthening this portion by means of a rod of ebonite, which passed up through the centre of the coil and through a slot, I, in the upper ebonite plate, and was clamped firmly after the adjustment of the instrument by an ebonite thumb screw, H. This, however, increased

* A Paper read before the American Association for the Advancement of Science at the Montreal Meeting, August, 1882.

Digitized by Google

the difficulties of adjustment. When the coils were adjusted to silence, then the tightening of the thumb screw H, disturbed the balance; and if the thumb-screw H was tightened first, then the adjustment could only be made by a series of jerks, on account of friction. In practice we found it best to adjust the instrument *almost to silence*, and then the tightening of the thumb-screw H completed the balance.

This was the form of apparatus at which we had arrived at the time of the death of President Garfield.

The difficulty of adjusting the coils led me ultimately to the idea of the apparatus shown in Figs. 21, 22, 23, 24, which is the most practical form of the instrument yet devised.

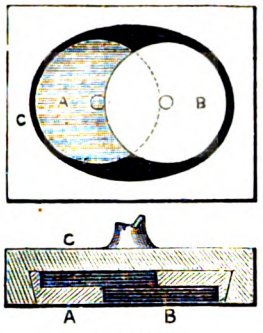

FIG. 21.

The two exploring coils A B (Fig. 21) are arranged as shown, in a recess turned out in a single block of wood C.

The coils are temporarily connected with a telephone, battery and rheotome in the manner shown in Fig. 1, so that they may be adjusted by hand to form a balance. When they have been arranged in their position of silence, the hollow in the block of wood C (Fig. 21) is filled with melted paraffin. Upon cooling, the two coils are found immovably fixed in one solid cake of paraffin.

As a matter of practice it is found impossible to fix the coils in this way exactly in their position of silence; but by means of two other very small coils, D E (Fig. 22) of insignificant resistance, forming a sort of fine adjustment external to the explorer, a perfect balance is easily obtained. In this instrument the swaying of the coils A B produces no effect upon the balance.

FIG. 22.

FIG. 23.

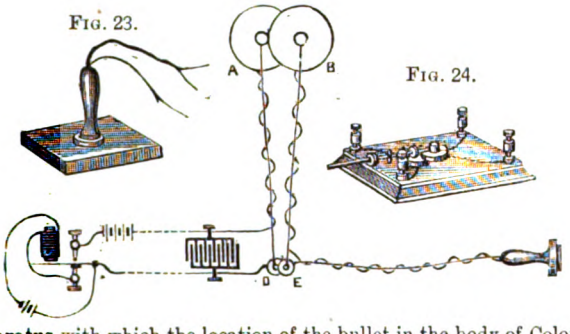

FIG. 24.

Apparatus with which the location of the bullet in the body of Colonel Clayton was discovered, October 7th, 1881.

The completed arrangement is shown in plan in Fig. 22, and the explorer and balancing coils are shown separately in perspective in Figs. 23 and 24.

On account of the small size and slight resistance of the balancing coils we were enabled to make the adjustable parts of the balancer of metal without practical interference with the sensitiveness of the exploring instrument, and this gave us the power of making very delicate adjustments of the balancing coils.

We found it advisable, however, to avoid placing metal over the sensitive area of the coils as had been done in the instrument shown in Fig. 24.

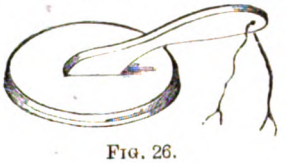

FIG. 26.

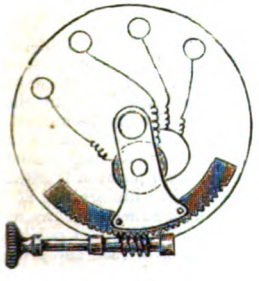

FIG. 25.

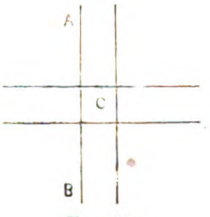

FIG. 27.

In the balancing apparatus shown in Fig. 25 (which is the most perfect one yet constructed), the lever to which the upper coil is attached is made of hard rubber.

In Fig. 26 is shown the most convenient form of case yet devised for holding the exploring coils.

By invitation of Dr. Frank Hamilton experiments were made with it at his office in New York, October 7, 1881, the instruments used being those shown in Figs. 22, 23, 24.

As this was the first successful application of the Induction Balance to the discovery of the situation of a ball in the body the position of which was previously unknown, I may be pardoned for entering somewhat into detail.

I shall quote from the *Medical Gazette*,* of New York, an account of the experiments written by one of the witnesses:—

The First Successful Application.

"On Friday, Oct. 7, by invitation, several medical gentlemen,† including the writer, met Professor Bell at the house of Dr. Frank H. Hamilton, in this city, for the purpose of witnessing the practical application of his improved instrument.

"The first person subjected to experiment was General Calvin E. Pratt, judge of the Supreme Court of the State of New York, and who is now a resident of Brooklyn. General Pratt, at the battle of Gaines' Mills, June, 1862, this being the second day of the famous seven days' retreat across the peninsula, received a ball in his left cheek, which penetrated through the nares and was lodged in the right antrum. Its presence at this time was recognised by his surgical attendant, Dr. Damainville, and its exact position has been known from that day until this, it having given rise at times to much pain and suffering.

"General Pratt has been seen by Dr. Hamilton and Dr. Damainville occasionally from that time forward, and they have from time to time urged upon him the necessity of its removal. General Pratt, however, was anxious to know whether Professor Bell's instrument would indicate its presence at the same point as declared by his surgeons.

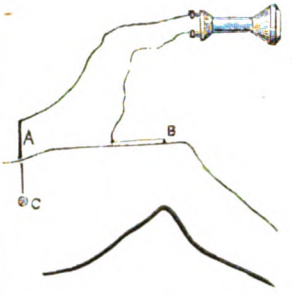

FIG. 28.

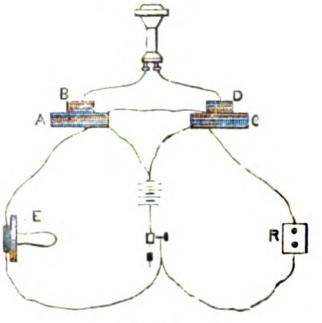

FIG. 29.

"The results of the experiment were conclusive and entirely satisfactory to General Pratt, the response being heard distinctly, but rather feebly, by every person present in the room. The feebleness of the response was supposed to be due to the fact that, owing to its situation and the peculiar form of the instrument containing the induction coils, it was impossible to bring the centre of its surface very near the site of the ball, the ball being situated very near the depression at the ala of the nose.

"The next patient was Colonel B. F. Clayton, who received a wound at the battle of Cedar Mountain, Virginia, Aug. 9, 1862.

"The missile was supposed to be an Enfield rifle ball, and the wound was supposed to be mortal by the medical director of General Banks's staff and his assistants. The ball passed through the sternal end of the left clavicle, and was supposed to have lodged in the muscles under the superior angle of the corresponding scapula. The injury was followed by complete paralysis of the left arm, continuing for a period of six months; and his arm has never yet been completely restored to its normal condition. He suffers a great portion of his time from pains in the arm, shoulder, and portions of the back.

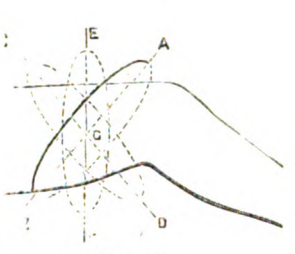

FIG. 30.

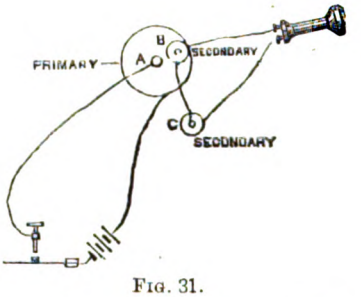

FIG. 31.

"Several small fragments of bone escaped through a fistulous orifice formed near the seat of the original wound.

"About eighteen months later an abscess opened on the front of the chest below the fifth rib and to the left of the sternum. Through this sinus his surgeon was able to carry a probe upwards and backwards towards the top of the shoulder several inches, and which sinus was supposed then to communicate with the seat of the ball on the back.

"Pleural adhesions were recognised by the medical attendant as having occurred in the upper part of the left thoracic cavity. He has been troubled occasionally ever since the injury with cough, expectoration, and

* See *Medical Gazette*, Oct. 15, 1881, pp. 347-349.

† "The following are the names of the medical gentlemen who were present, each one of whom verified personally the results and declared his entire satisfaction with every experiment that was made: J. C. Hutchinson, J. G. Johnson, and J. G. Allen, of Brooklyn; Elias Marsh, of Patterson, N.J.; Nathan Bozeman, J. H. Hunter, G. Durant, F. Delafield, L. Damainville, W. M. Chamberlain, J. H. Girdner, Frank H. Hamilton, and E. J. Birmingham, of New York."

Digitized by Google

violent palpitations of the heart. A suspicion has even been entertained that the fistulous canal which remained open a period of eighteen months, and then became permanently closed, communicated with the bronchial tubes, but at no time was a suspicion entertained by him or his medical attendants that the ball was not lodged in the back and there closely encysted.

"We are disposed to mention as an evidence of Colonel Clayton's loyalty and faithfulness as a soldier that within six months of the receipt of the injury, and while the wound was still discharging pus and blood, he returned to active duty with his regiment and remained in the field until the close of the war.

"In the presence of the gentlemen assembled Colonel Clayton exposed his chest, and Professor Bell proceeded to move the coils across that portion of his back where the ball was supposed to be situated, the Colonel indicating the point underneath the superior angle of the scapula as that which had been fixed upon by himself and all the surgeons who had examined him as its exact seat. Although being buried underneath the scapula they had not been able to verify their diagnosis by the sense of touch. Repeated examinations were made over this region without any response both by Professor Bell and several of the gentlemen who were present.

"The instrument was then moved in every direction across the back and shoulders with the same result. There was an evident feeling of disappointment on the part of Professor Bell and all the gentlemen present, for no one entertained a doubt up to this moment that the situation of the ball was known and correctly stated by Colonel Clayton.

"It was not until the lapse of half an hour, and a thorough examination on the part of Professor Bell to determine if there was not some imperfection in the working of the apparatus, that it was suggested to move the instrument along the front of the chest.

"This was done by Professor Bell, and immediately he exclaimed, 'I have found it!' And such was evidently the fact, as was verified by the personal examination through the telephone by every gentleman present. The response when the instrument was moved over the seat of the ball was loud and distinct, and left no room for doubt."

After all the visitors present had had the opportunity of verifying my discovery of the sonorous spot on the chest of Colonel Clayton, experiments were made to determine as accurately as possible the exact position of the ball.

The exploring instrument (Fig. 23) was first held over that part of the chest where the maximum sound was obtained. The instrument was then moved slowly towards the left until the sound could no longer be perceived. The position of the centre of the instrument was noted, and a vertical line (A B, Fig. 27) was drawn with ink upon the skin through that point. This line indicated the boundary of the sonorous area towards the left. The experiment was then repeated by moving the instrument from the point of maximum sound towards the right, and also upwards and downwards, giving us the four boundary-lines shown in the diagram (Fig. 27). The bullet was thus located within a square, C, of about one inch.

"The exact situation of the ball," as described in the *Medical Gazette*, "was found to be within the thorax, probably in immediate contact with the inner surface of the ribs, the point being a little to the left of the sternum, between the third and fourth ribs, and two or three inches above the cicatrix on the front of the chest, where the sinus, long since closed, had evacuated itself, and in a direct line from this cicatrix towards the left shoulder, which indicated the line of the track of the original sinus."

Experiments with Needles.

During my absence from Washington and from all conveniences for experimenting personally with induction balance apparatus, I devised a method of verifying the indications of the induction balance and of ascertaining the exact depth at which a bullet lies beneath the surface. This method was communicated through Dr. Woodward to the surgeons in attendance on President Garfield, and it was made the subject of a special paper presented to the French Academy of Sciences, Nov. 7, 1881.

This method, although involving extremely slight pain, would ordinarily be used only as a preliminary to an operation for the extraction of a bullet. The arrangement is shown in Fig. 28. A fine needle, A, is connected to one terminal of a telephone, and the other terminal makes contact with a plate, B, preferably of the same material as that composing the needle. Place this metallic plate B against the surface of the patient's skin, and thrust the needle into that portion of the body where the bullet is believed to be lodged. When the point of the needle makes contact with the surface of the bullet C a galvanic battery will be formed naturally within the body, the two poles of which are respectively the leaden bullet C and the metallic plate B. Under these circumstances a click will be heard from the telephone each time the bullet is touched by the needle. This has been verified by experiments upon bullets buried in a joint of meat. The click, though feeble, is unmistakable.

I have no doubt that this method of exploration alone, without the induction balance, would prove of great service upon a field of battle, where the employment of complicated apparatus is impossible. Mr. Thomas Gleason has recently communicated to me the particulars of an experiment he witnessed, in the course of which this method was tried upon a living subject. The surgeon who conducted the experiment was unable to obtain any response from the induction balance employed, although from certain indications apparent to the sense of touch he believed that the bullet was located in the part of the body submitted to experiment.

To verify his supposition, a needle connected as above (Fig. 28) was thrust into contact with the hard substance perceived, but no response was made by the telephone. The surgeon, however, believing that the bullet had been found, etherised his patient, and proceeded with an operation, but discovered, when too late, that the bullet was not there.

Further Modifications of Induction Balance.

I sailed for Europe early in October, 1881, and have had no opportunity since of continuing my researches until quite recently. While I was in Europe, however, Mr. Sumner Tainter devised a new kind of induction balance which deserves mention here. The results obtained with this apparatus in its present form (Fig. 29) are not to be compared with those produced by the best instruments described above, but there are undoubtedly great possibilities of future development.

The important feature is that the exploring instrument E consists of *a single coil*, so that there is no possibility of any part of the explorer getting out of adjustment. All the adjustments are made upon the stationary part of the apparatus.

The current of the battery is divided between two equal circuits. One of the primary circuits contains the coil A and the exploring coil E, and the other circuit the coil C and a rheostat R. Coils A and C are exactly similar; and if the resistance introduced at R is equal to the resistance of the exploring coil E, an acoustic balance can be obtained by the adjustment of the secondary coils B D upon the primaries A C; but if the resistance introduced at R is different from that at E, Mr. Tainter states that no balance is possible.

When the apparatus is adjusted to silence the approach of a bullet to the coil E destroys the balance.

Although the great object of the researches that have been brought before you to-day has been to find that arrangement of balance which will detect a bullet at the greatest distance from the coils of the explorer, it must not be forgotten that in every case the instrument is more sensitive to the presence of a bullet placed *inside* the exploring coils than to one exterior to them. When, therefore, we seek the location of a bullet in one of the limbs, it may be advisable to use an annular coil large enough to slip easily over the leg or arm, as the case may be.

In Mr. Tainter's arrangement the exploring coil E (Fig. 29) might simply be a large ring consisting of a number of convolutions of thick wire which could be slipped over the limb, or the ring might consist of two coils, forming one side of a Hughes Induction Balance.

In either case the loudest sound will be produced when the bullet is in the plane of the ring, and its exact location should be deduced from three observations. Suppose, for instance, that with the ring inclined in a particular direction the maximum sound is obtained when the ring occupies the position A B. (Fig. 30). We know then that the bullet is in that plane. Now, incline the ring in some other direction and explore again. Let the position of maximum sound be now C D. We know then that the bullet is somewhere on the straight line formed by the intersection of the planes A B and C D. It is only necessary then to make a third observation with the apparatus so inclined that the plane of the ring cuts this straight line, for instance, the position E F. The point of intersection of the three planes G is then the exact point occupied by the bullet.

I shall conclude this paper by the description of an experiment made in Newport, R. I., a few days ago. The results are so unprecedented in my experience that I feel they cannot be received as implicitly reliable until the experiments have been repeated and verified.

I had arranged upon a table three coils (as shown in Fig. 31). The large flat primary coil A was connected with a battery of four Bunsen elements and an interrupter, as shown, and the two small secondaries of fine wire B C were connected with a telephone.

The secondary B was moved about on the primary A until a position of silence was obtained. Upon bringing a leaden bullet near C the balance was disturbed and a distinct sound produced from the telephone. There is nothing very strange about this when we know that the distance between A and C was only 15 centimetres, so that C was well within the field of induction of A; but what did seem extraordinary was that the approach of the large steel blade of a penknife to the coil C produced no effect! The iron diaphragm of a hand telephone brought close up to the coil C produced no sensible disturbance of the balance, whereas a small disc of lead produced quite a marked effect. A disc of copper the size of a telephone diaphragm also produced a good effect, but the sound was not sensibly louder than that due to the small leaden disc. A diaphragm of zinc occasioned a feeble, but distinct, disturbance of the balance. It is, unfortunately, the case that in all the forms of induction balance described above lead gives the poorest effect of all metals. If people would only make their bullets of silver or iron there would be no difficulty in finding them in any part of the body! In the apparatus shown in Fig. 31, however, it seems (unless subsequent experiments should reveal some fallacy) that we have an arrangement which is sensitive to lead and not to iron, or, at at all events, which is more markedly influenced by lead than iron.

It is hardly necessary to state that, when the coil C was removed to a considerable distance from the primary A, no effect was produced by the approach of metal to the coil C.

I have in this paper brought before you an outline of a labour of love pursued through many anxious days and sleepless nights. However imperfect or disappointing may be the results so far achieved, they are sufficiently encouraging to enable us to look forward with confidence to the attainment of still greater perfection.

I hope to continue these researches in the future; and certainly no man can have a higher incentive to renewed exertion than the hope of relieving suffering and saving life.

THE DEVON AND CORNWALL ELECTRIC LIGHT AND POWER COMPANY (LIMITED).

An extraordinary general meeting of the members of this Company was held at the Cannon-street Hotel on the 10th inst., "for the purpose of considering the present position of the Company, and (if it should be deemed expedient) to pass the following resolution:—That in the interests of the large majority of the shareholders of the above-named Company, the said Company do, on the hearing of the petition of Henry Whorlow for the winding up of the above-named Company, consent to an order being made by the judge to whose court such petition is attached."

Mr. W. H. Owen presided, and alluded to the decision arrived at by the previous meeting to oppose any legal proceedings as well as any attempt that might be made to wind up the Company. Mr. Whorlow's petition contained several allegations, and many of them stated that the prospectus was incorrect as to the Lane-Fox lamp. He then stated that the Company was now sued by thirty-seven shareholders, who were endeavouring to obtain the return of the money which had been paid by them on their shares. The directors had, in these circumstances, considered it right to call the shareholders together, for it would be most unfair that a portion of the shareholders should get back 20s. in the pound at the expense of the other shareholders, who, to meet such claims, would have to pay another call. The directors believed that it would be to the advantage of th majority of the shareholders that they consent to an order being made on

Digitized by Google

Mr. Whorlow's petition, inasmuch as they were advised that an order would take effect from the date of the presentation of the petition, namely, November 1st last, and such proceedings of hostile shareholders had been commenced subsequent to that date. Those shareholders would only rank equal with all the other shareholders in the distribution of the assets. If, however, Mr. Whorlow's petition were dismissed by the Court the hostile shareholders might obtain priority over the other shareholders. He concluded by proposing the resolution.

Mr. G. BRAGGINTON seconded the motion, and suggested the advisability of appointing a small committee in connection with any claim this Company might have against the Great Western Electric Light Company for misrepresentation as to the sale of their concessions to this Company.

At the request of Mr. Fewings, the voting power of the meeting was counted, and the chairman said that the proxies forwarded in favour of the resolution represented 603 votes and the shareholders present had 418 votes.

Mr. FEWINGS stated that he was in entire accord with the resolution which had been so ably proposed by the chairman. From the contents of the circular accompanying the notice convening the meeting it must strike everyone who had carefully considered it that the only course open to the shareholders was to prevent the hostile shareholders from being transformed, as they would be if the petition were not assented to, into creditors of the Company, who would be entitled in that case to receive full payment of their money. He wished to know if a legal opinion had been taken on a matter of very grave and serious importance. A mistake, to say the least of it, had unfortunately crept into the prospectus, a mistake which had left Mr. Justice Chitty to make an order on the application of the Hon. W. F. Cadogan on the ground of misrepresentation. That misrepresentation was due to somebody, and he wished to know if counsel's opinion had been taken as to the origin of the error, and who was responsible for it.

The CHAIRMAN stated that counsel's opinion had been taken, but the present was not an opportune moment to go into the question as to who was liable for the mistake. In case of the Company going into liquidation it would be the duty of the liquidator to go fully into this matter and to press their claims if necessary. He was strongly of opinion that some one was liable. The opinion given to the directors was a very unsatisfactory one, because it was to the effect that a general mistake had occurred all round and under a state of things in which it would be very difficult to make any individual liable. That was the whole purport of the opinion which had been given by Mr. Romer, Q.C. He did not agree with the opinion, and it would become the duty of the liquidator to press the matter and obtain a judicial opinion on it.

Mr. HENRY MAUDSLAY stated that about a third of the shareholders of the Company was not represented at the meeting either by person or proxy. There were thirty-seven shareholders who had brought actions, but there were only thirty-six on his paper who represented 3,267 shares of an amount of £8,617. If each of those shareholders had his money returned in full the Company would be in a very serious and anomalous position, and they would have to make another call on the shareholders to obtain a sufficient amount of money to be divided among those shareholders who had been litigious. He then referred to the anxious time which the directors had had, and to the onerous duties which had been discharged by Mr. Owen, the chairman, who had endeavoured to look after the interests of the shareholders in every possible way, while the expenses had been cut down to the greatest extent. Three of the members of the Board were original directors. He himself became a director from the force of circumstances, having been connected with the Great Western Company, and having taken 1,000 shares in this Company, every one of which he still held. He did have an opportunity of making a considerable profit out of those shares, but he had not trafficked in them. He still remained a director of this Company in the hope of being able to represent the interests of the shareholders. There were other similar companies who had fallen into the same error as this Company had, and there had been considerable difficulty from this circumstance throughout the country. Owing to this unfortunate mistake, whoever was responsible for it, they were now suffering for it as shareholders, but the best possible way was to endeavour to get out of it with the least possible cost. The directors were obliged to confess that an error had been made, but not by them. The Devon and Cornwall Company was a sub-company of the Great Western Company, and they purchased from that company something which it appeared the Great Western Company did not possess to sell. It was possible that they might be able to put things in such a way as to induce the Great Western Company to return the money, this Company giving back the concessions. He had asked the Board of the Great Western Company to consider whether, under the circumstance of their having sold what they did not possess, they would not give this Company back what had been paid to them. That was the principal reason why he left the Board of the Great Western Company. With regard to the claims on the Company, they amounted, as he had said, to £8,617, and they had now owing £4,200, and unpaid calls amounting to about £3,000. On the 16th November they had £5,153 in hand.

A SHAREHOLDER: The uncalled capital and the money in hand will about meet these claims?

Mr. MAUDSLAY replied in the affirmative.

Mr. BRAGGINTON considered the explanations they had received very satisfactory, and thought it would be most wise, under the circumstances, to agree to the course which had been adopted.

Mr. PARSONS, on behalf of the Great Western Company, whose proxy he held, said he should not vote for or against the liquidation, but he should leave the question entirely in the hands of the shareholders.

Mr. FEWINGS said a most material point occurred to him in connection with the resolution which had been made by Mr. Parsons. At the last meeting the chairman stated that there was a clause in the contract whereby this Company bought the electric light of Devon and Cornwall from the Great Western Company to the effect that if they resolved on liquidation, or the Company get into any shape of winding up, they would actually forfeit by that step all rights against the Great Western Company or any claim for the return of the money they had paid, and that the licenses acquired from the Great Western Company would revert to the Great Western Company, and that the Devon and Cornwall Company would get no compensation whatever. He (Mr. Fewings) thought that a very unbusinesslike clause, and he desired to know if they had been advised since that they would not forfeit the license by winding up.

The CHAIRMAN, in reply, stated that when the agreement was made with the Great Western Company, whereby it was provided in case of coming to a winding up of this Company the concession should revert to the Great Western Cpmpany, it was never supposed for a moment that there was going to be such a state of things as now existed, namely, an error in the very thing which the Great Western Company was selling to this Company. They had only, however, to do one of two things—to wind up, or to go on. If they went on, a further call would be made probably to the extent of all the unpaid capital to meet the claims upon them, so that on the one hand they would have an empty concession, and on the other all these hostile proceedings. A communication had been made to the directors of the Great Western Company with regard to the return of the money paid them by the Company, but it came to nothing, because the Great Western Company repudiated all liability whatever.

After a slight further discussion, the CHAIRMAN put the resolution as above, and declared it carried unanimously.

Some further discussion took place with regard to the suggestion made by Mr. Bragginton as to whether a committee should be appointed to advise and to watch over the liquidator.

Mr. RYLANDS (the solicitor of the Company), however, alluded to certain objections against the appointment of the committee, stating that a Court always looked rather jealously on any interference, and further stated that the committee would cause additional expense.

The CHAIRMAN said that the directors would give every assistance they could on behalf of the shareholders, and that they would do their utmost throughout to protect the interests of the Company. He expressed his unabated confidence in electricity, and the thanks of the directors to the shareholders for their kindness and forbearance.

On the motion of Mr. MORTIMER, seconded by Mr. MAUDSLAY a vote of thanks to the chairman brought the proceedings to a close.

WESTERN AND BRAZILIAN TELEGRAPH COMPANY (LIMITED).

The tenth ordinary general meeting of this Company was held at the City Terminus Hotel on the 10th inst., under the presidency of Sir H. D. Wolff, M.P.

The SECRETARY (Mr. R. M. Cunningham) read the notice convening the meeting, and the report of the directors, which has appeared in *The Electrician*, was taken as read.

The CHAIRMAN, in moving the adoption of the report, referred to the negotiations with the Brazilian Government, to which he alluded last year, which were being carried on at that time by Mr. Cunningham on behalf of the Company. These negotiations could not be considered as concluded. As he said last year, the question was one of great delicacy, affecting not only the Company's relations with the Brazilian Government, but also their relations with other telegraph companies; and thinking that it would take some time to carry them out they thought it better to place their house in order in this country—to place themselves in as good a position as possible, as they thought it was due to them to strengthen their position in connection with these negotiations. Last year a commission was appointed by the Brazilian Government to look into the negotiations and proposals which Mr. Cunningham was instructed to carry through, and the Government generally, and he believed the Brazilian public, looked with considerable favour on the Company's proposals. In a country, however, which was subject to constant changes of government, and where questions of this nature were submitted to the decision of the popular assembly, it appeared to the directors, as he had said, that the negotiations would take a considerable time before they could be carried through, and Mr. Cunninghamwas consequently instructed to return to England. They still believed that the Brazilian Government looked favourably at their proposals, and that at some time or other not specified, but he hoped not very remote, they might be able to recommence negotiations with the Government. Turning to the report, he stated that they had opened communications with Maldonado and Ceara. As regarded Maldonado they had not to lay any new cable, as it already existed, but there was no station, and the Uruguayan Government requested the Company to open a station there, and had given the Company a subsidy sufficient to pay the working expenses, and therefore there could be no loss there, and he hoped there would be a profit. As to Ceara they had opened a new station in that very important and rising place, and had done so by laying an entirely new line between Maranham and Ceara, thus dividing the section which originally went from Maranham to Pernambuco. They had also entered into a contract for the purchase of a new repairing ship, and their reason for doing that was on account of the great length of the Company's system, which altogether, with the lines they worked for others, was 3,700 miles. By having two steamers, one at either end of the line, they would not only improve their communications altogether, but save a very large sum of money which they were annually exposed to lose by the length of time which it took to make repairs. They thought that the price of the steamer would be fully recouped by the lesser time occupied in repairs. With regard to the earnings, they had to a certain extent decreased since last year, but still the total receipts were comparatively satisfactory. The working expenses had been reduced by £8,500, and the maintenance for the year decreased by £10,000. One of the great causes of the bad returns of the Company had been owing to a cable having been originally laid which was not suited for the purposes required. A deep sea cable was laid in shallow water, and was exposed to risks to which a sheathed cable was not exposed. They had found that wherever there had been a sheathed cable the repairs had been very insignificant and very rare, whereas where the old type of cable had been laid the interruptions were very frequent. Therefore, a very large sum had at different times been spent, not merely on ordinary cursory repairs, but on renewal of the lines, and the result was to a large extent satisfactory to the Company; for though they had spent £41,000 a year on repairs, together with certain sums charged to capital, they had out of a total line of 2,500 miles, new cable for a length of 1,500 miles, and therefore three-fifths of the cable had been entirely relaid, and might be considered to have given a new lease to that portion of their system. They also at the present moment possessed money by which they could, if they thought it right, relay the whole of the rest of the line. They trusted, however, that that would not be necessary, because the deep sea cable lying n

Digitized by Google

deep water, the interruptions and accidents were not frequent, and they considered at the present moment that their cable was in a very fair state of repair, and would only require comparatively small renewals and alterations and repairs for the next few years. Although the earnings during the past year had shown a small reduction to those of the preceding year they were now to a certain extent recovering, and for the first quarter of the current year, namely, from the 1st of October to the 31st December, the traffic had shown an increase of something over £3,000. They had now finally closed the litigation which had been going on, and had received an additional sum of money, and the question now before them was the reduction of the capital with the view of paying a dividend. They had applied to some distinguished counsel—the Attorney-General and Mr. Horace Davey, Q.C.—with the view of inquiring how they might proceed under the new prospects of the Company, and not only had they submitted cases to counsel, but the directors had on more than one occasion had interviews with them, and the course they were now adopting was one recommended by those two eminent gentlemen. The project was to reduce the share capital of the Company by a sum of money representing £5 a share, which would include the whole loss on the central American cable and also certain depreciation of instruments and renewal of cable and repairs of the ship which heretofore had not been dealt with. It would be the duty of the directors to ask the shareholders their consent to this reduction of capital, by which means they would have a sum of money which, as soon as the Court had ratified the proposal—which he hoped would not take very long—which would enable them to declare a dividend equal to 3 per cent. on the whole of the reduced capital and to place £12,000 to reserve and carry forward a balance. He could not help thinking that this course would recommend itself to the approval of the shareholders, because it was perfectly plain that there was no good counting as capital what was not capital, and the shares were really not reduced in value by the frank admission that a loss had been made and they had written it off. For a long time £15 per share had been the real capital of the Company, and on that £15 a share he trusted that they might be able to keep up a dividend. In fact, by the recovery of so large a sum as that now standing to the Company's credit, they would be able fairly to expend sums on renewal out of the amount recovered which had hitherto been very unfairly placed upon revenue owing to the exigencies of the Company. As to the question of dividing the shares into preferred ordinary shares, bearing 5 per cent. cumulative dividends, and into deferred ordinary shares, the division had been forced on the directors in a manner so influential that they had no alternative but to put it before the meeting. But he might say that it would be quite optional on the part of the shareholders to avail themselves of the division. Those who preferred keeping their shares as they were at present, and not dividing them, would have their dividends paid on their shares as they stood—£15 each. The proposal would simply enable those who chose to divide to do so. He did not care to hold out hopes which might not be realised, and they all knew the great vicissitudes which the Company had gone through. But at the same time it was his hope that they would be able to keep up a dividend, and meanwhile they proposed, as soon as they found themselves released from the labours which the consideration of this reconstruction had given them, to turn their attention once more to the question of the negotiations with the Brazilian Government. Notwithstanding the competition of the Brazilian land lines, which was really very unfair competition, the Company did not do so badly as might be anticipated, because their service was superior to the Brazilian service in speed, accuracy, and, he thought, secrecy, and those qualities were appreciated by the Brazilian Government, as was shown by the fact that, notwithstanding the competition of the Brazilian Government lines, the Company still kept up their traffic pretty much to the old figures. He concluded by moving the adoption of the report and accounts.

Mr. W. S. ANDREWS seconded the motion.

The CHAIRMAN, after having replied to a few questions, intimated that the directors had considered it their duty, having regard to the enormous labours and the success attending them which had been undertaken by the managing-director (Major Wood) and by Mr. Cunningham, to give those gentlemen a substantial recognition of their services out of the funds of the Company. They had allotted to Major Wood £1,500, and to Mr. Cunningham £750.

The motion was then unanimously adopted, and the retiring directors and auditor were afterwards reappointed.

Mr. PIKE then alluded to the value of the services which the directors had rendered in getting back for the Company no less than £140,000 from persons formerly connected with the Company. It would not be considered wrong by commercial men to give them 5 per cent. on the amount recovered; but he was not going to make such a proposition. But it was his intention to move a resolution (which he afterwards formally submitted), requesting the directors to give notice for the next meeting that a proposal would be brought forward to transfer to the directors, in recognition of the services to which he had alluded, 700 of the shares which had been given back as part of the arrangement made in connection with the late litigation.

Mr. SUTTON seconded the motion, which was supported by Sir W. P. Andrew.

Some further discussion took place respecting the matter, in the course of which

Captain COTTON did not agree with burdening the Company as was proposed, and thought that each shareholder who appreciated the action of the directors should himself out of his own pocket show his appreciation of that action. For his own part he held 100 shares, and was prepared to give 10 per cent. out of his dividend. He afterwards moved an amendment to the effect that the matter should be postponed till they paid a dividend.

Mr. PIKE put the amendment and the resolution, and declared the latter carried.

An extraordinary general meeting was then held, and the chairman moved the first of the special resolutions of which notice had been given, reducing the capital from £1,398,200, divided into 69,910 shares of £20 each, to £1,048,650, divided into an equal number of shares of £15 each.

Mr. C. W. EARLE seconded the motion, and it was carried unanimously.

The CHAIRMAN, in reply to a question, stated that they would have to apply for a new quotation to the Stock Exchange for the preferred and deferred shares, the ordinary shares remaining as they were. He then moved the second resolution, dividing the shares as proposed. The motion having been seconded,

Mr. ROKEBY PRICE did not think the Committee of the Stock Exchange, of which he was a member, would have any difficulty in giving a quotation to the shares. But he objected to the proposal as a principle. He contended that it would be no advantage whatever to the shareholders to split the shares into two classes. There would be no more capital and no more earnings, but the only thing that it would do would be to produce enormous fluctuations in the value of the preferred and ordinary shares; and as regarded those who retained their shares as at present and did not divide them, they would find, as in other cases, that there was no market for them. They would, in short, have a useless division, and the only effect would be that there would be a great increase in speculative transactions. He believed he was expressing the best opinions on the Stock Exchange in making these remarks against the proposed division of the shares.

Mr. COTTON acquiesced in the remarks of Mr. Price.

The CHAIRMAN stated that they had two sets of proxies, one relating to the business of the ordinary meeting and the other for the extraordinary meeting, and, therefore, those who had sent their proxies for the extraordinary meeting were clearly in favour of this resolution, and he must put the motion, which he proceeded to do. He announced that the resolution was lost on a show of hands, and the directors did not consider it wise to have a poll on the subject, and, therefore, he considered that that proposition was negatived. He then moved the third resolution, substituting for Article 40 another article similarly numbered, authorising the Board to appoint a managing director who might be a member of the Board, but who should not be subject to retirement by rotation.

The motion was seconded and carried unanimously.

On the motion of Mr. PRICE, seconded by Mr. ROBINSON KENDAL, a vote of thanks to the chairman and directors terminated the proceedings.

SLIP

SPAIN.—The cable between Falmouth and Bilboa is interrupted.

BRAZILIAN SUBMARINE TELEGRAPH COMPANY.—The traffic receipts of this company for the week ended January 12 were £3,540.

BRIGHTON.—The Town Council have resolved to oppose the application of the Union Electric Light Company for a provisional order.

BIRMINGHAM AND MIDLAND INSTITUTE.—The presidency of the institute for the ensuing year has been accepted by Sir William Thomson, F.R.S., &c.

ELECTRICAL EXHIBITION AT VIENNA.—The regulations and conditions as to exhibits at this exhibition will be found in another page of this week's issue.

MR. FAWCETT.—The medical advisers of Mr. Fawcett are most urgent in insisting that he should have complete rest, bodily and mental, for at least two months.

STOCKPORT.—The Town Council of Stockport have abandoned their intention of applying for a provisional order to enable them to supply electricity for lighting and other purposes in this town.

UNIVERSITY COLLEGE.—Professor G. Carey Foster, F.R.S., was to have delivered a public lecture on "The Sources and Applications of Electricity" at University College, Gower-street, on Thursday evening.

THE ROYAL SOCIETY.—On Thursday, Mr. R. H. M. Bosanquet was to have read a preliminary paper before this society "On a Uniform Rotation Machine, and on the Theory of Electro-Magnetic Tuning Forks."

ELECTRIC WORKS COMPANY.—A meeting of this company is to be held at 3, Bucklersbury, E.C., on the 17th February, at 11 a.m., to receive an account of the manner in which the winding up of the company has been conducted.

AURORA BOREALIS.—A magnificent display of the aurora was witnessed at Lerwick, in the Shetland Islands, on Sunday night (the 7th inst). Local accounts describe it as even more brilliant than the display of December last.

DIRECT UNITED STATES CABLE COMPANY.—The board of this company have resolved upon the payment of an interim dividend of 5s. per share, being at the rate of 5 per cent. per annum, for the quarter ended Dec. 31, 1882.

STUDENTS' COLUMNS.—We regret to have again to postpone our Students' Column to a future issue; the continuation of our Review of the Year, and an unlooked-for length of Correspondence, have combined against us in this matter.

APPOINTMENT.—The directors of the Metropolitan Brush Electric Light and Power Company have appointed Mr. Radcliffe Ward, formerly chief electrical engineer to the British Electric Light Company, to be chief electrical engineer to their company.

ELECTRIC LIGHT AT LONG EATON (NOTTS.).—Some of the leading lace makers in this district have determined to adopt the electric light, and have placed the work in the hands of the Hammond Electric Light and Power Supply Company.

RESIGNATIONS.—Mr. J. Kenneth D. Mackenzie, A.S.T.E., has resigned the appointment of electrical engineer to the Metropolitan Brush Electric Light and Power Company.—Mr. D. P. Wingrave has resigned the managership of the London and Provincial Electric Lighting and Power Generating Company.

CUBA SUBMARINE TELEGRAPH COMPANY.—The directors of this company have resolved, after providing for the dividend on the preference shares, and placing £1,325 to the reserve fund, to recommend the payment of a dividend on the ordinary shares at the rate of 7 per cent. per annum, free of income-tax, leaving £1,074 to be carried forward to the current half year's accounts.

ORIENTAL TELEPHONE COMPANY.—An extraordinary general meeting of this company is called for the 24th instant, to be held at the Cannon-street Hotel, at 12 noon. The meeting will be asked to consider and pass certain resolutions rescinding and altering some of the Articles of Association, in order to confer upon the directors the power of declaring an interim dividend.

CONVERSAZIONE.—Last week the Birmingham and Midlands Institute gave their annual *conversazione*, in which electricity played an important part. Amongst other things, the operations of boiling and roasting by means of the current were shown to those present. A number of other familiar lecture experiments were also carried out. The current was supplied by Messrs. Winfield and Co.

NATIONAL TELEPHONE COMPANY, NOTTINGHAM.—The superintendent of the Nottingham fire station mentions that during the last year eight fires were reported by telephone through the Central Exchange and various police stations connected by the above company's system, and many thousands of pounds worth of property was saved owing to the rapid means of communication afforded.

ATLANTIC CABLE TRAFFIC.—It is stated that arrangements have been completed for the establishment of an independent submarine telegraph office in New York. The Direct United States and the Compagnie Française cables will be worked from this office, and will be entirely independent of the existing land wires in America, while they will at the same time be open to receive messages from any of the land wire systems of the United States.

ASSOCIATION OF CHAMBERS OF COMMERCE.—The twenty-third annual meeting of this association will take place on the 20th, 21st, and 22nd of February at the Westminster Palace Hotel. Amongst the subjects for discussion is a recommendation from the London Chamber to the effect that the Executive Council should prepare a report on the whole subject of inland postal and telegraphic reform. Proposals from other chambers regarding telephone communication, cheaper short telegrams, &c., will also be considered.

ELECTRIC LIGHTING CONTRACTS.—The Electric Carbon Storage and Apparatus Manufacturing Company of Leith have secured contracts for lighting the whole of F. Fowler and Co.'s Steam Plough Works, requiring 80 arc lamps and 900 incandescent lamps.—Messrs. Key and Son three steamers, with arc lamps for loading, &c., and incandescent for state cabins, saloons, &c.—Messrs. Kelly and Co., Kingston Works, by means of storage batteries and dynamo.—Messrs. Hyams' establishments in Edinburgh and Glasgow, and one of the Edinburgh theatres.

THERMO-ELECTRIC BATTERIES.—We have often pointed to this branch of electricity as offering a fine field for investigation, and no doubt shall soon find that many minds have been attracted in this direction. Dr. Paget Higgs tells us that he has long been making experiments with a view to practical work in domestic lighting, and that he has at length devised a system which answers well. The thermo-battery he has invented is unique and of a single metal, actuated by the ordinary fire and connected with a storage battery. We

Digitized by Google

have before us a pretty full description of the system, but at present it would be impolitic to say more on the subject.

THE "SUN" LAMP.—This lamp, as supplied by the Electric Sun Lamp and Power Company, of St. Margaret's Offices, Victoria-street, Westminster, has just been installed at Messrs. Singleton and Cole's premises, Wolverhampton, with success. It is also being erected at Messrs. Finlay and Co.'s Lace Curtain Works, Doune, Scotland, the Bowling Iron Works, Bradford, and establishments at Glasgow, Salford, and elsewhere. The central station of the company, 6, Riding House-street, Portland-place, W., is now complete, and application has been made to the local vestry to light a part of London from that centre. An exhibition of the light will shortly be made at the station.

THE FERRANTI-DYNAMO MACHINE.—We are informed that at Messrs. Copestakes, Hughes, and Crampton's works at Nottingham, where the first Ferranti installation has been made, it is found possible to turn out any number of lights without altering the speed of the dynamo machine. At the present time there are 100 C Swan lamps in use there, and recently, on the occasion of an inspection of the lights, one block after the other was turned out, until only one was left burning in the engine house. This installation has given so much satisfaction that it is, we understand, about to be increased to 500 lights. The work has been executed by the Hammond Electric Light and Power Supply Company.

ELECTRIC LIGHTING OF SHIPS.—The "Hawarden Castle," a new steamer recently built for Messrs. Donald Currie and Co.'s South African Mail Service by Messrs. John Elder and Co., of Fairfield, Govan, on the Clyde, is to be lighted by means of incandescent lamps. She was only launched last week, and was christened by Mrs. Gladstone, wife of the Premier. The "Hawarden Castle" is 393ft. 6in. long over all, 48ft. broad, 33ft. deep, and has a gross tonnage of about 4,300 tons. The "Ionic," another new steamer, recently built for the White Star line of American steamers by Messrs. Harland and Wolff, of Belfast, is to be lighted by the same system. She is 440ft. long, 44ft. broad, 32ft. deep, and has a gross tonnage of 5,000 tons.

AN ARMY TELEGRAPH CORPS.—At the recent distribution of medals to those members of the Post Office Volunteer Corps (24th Middlesex) who took part in the Egyptian campaign, Colonel Du Plat Taylor announced that he had received through Colonel Clive a despatch from the Secretary for War, granting him permission to raise two companies of Volunteer Telegraphists to form part of the Post Office Volunteers. These companies will have a purely Volunteer organisation, but will be instructed in the duties of Army Field Telegraphists. The medals were presented by the Duke of Teck, the recipients being Captain Viall, three sergeants, two corporals, and 28 men. Major G. C. Sturgeon, who commanded the detachment in Egypt, received his medal from Her Majesty the Queen some weeks since.

TELEGRAPHISTS AND HOTEL KEEPERS.—At the Berkshire Assizes, held at Reading last week, Thomas Pocock, proprietor of the Bacon Arms Hotel, Newbury, was charged with refusing to accommodate four telegraph clerks. In September last Lord Carnarvon delivered a speech at Newbury, and four telegraph clerks were sent from London to transmit it to the morning papers. The clerks engaged beds at the Bacon Arms Hotel, but as they did not return until nearly three in the morning the landlord refused to admit them. It was raining heavily at the time, and three of the clerks became ill in consequence of exposure, having had to remain out all night. For the defence it was alleged that the clerks were abusive and could have come to the hotel earlier. This was denied. Mr. Baron Huddleston said that all keepers of hotels were bound to accommodate travellers. He ordered the defendant to be bound over in his recognisances of £100 to come up for judgment if called upon.

TATE'S ENGINE STOPPER.—Some weeks since (see *The Electrician*, October 21) we illustrated and described Tate's electric apparatus for closing the valve of an engine and thereby stopping it. This apparatus is now at work in some of the large mills at Dundee, in Scotland. In describing the apparatus at work, the *Dundee Advertiser* of Tuesday last says:—"The huge engine in Manhattan Works (Colonel Sandeman's), working at from 600 to 700 horse-power, and driving a fly-wheel of about 35 tons weight, formerly took two minutes to come to rest after the steam had been taken off. This apparatus has been fitted to it, and the ponderous engine is now brought up in thirty seconds. To see this powerful, majestic piece of machinery, the developer of power for a large range of works, almost immediately brought to a standstill by the mere touching of a button at the far end of the building is an impressive illustration of the easy control of enormous force by wisely ordered arrangements. To mill-owners the utility of the apparatus will be evident."

EDISON'S SYSTEM IN MELBOURNE.—The *Melbourne Age* for November 29, a copy of which we have just received, says:—"The chamber of the Legislative Council was lighted by Edison's electric light last evening. When the members met the room was lighted as usual by gas, the large glass chandelier only being used. About six o'clock the standard gas lights were lighted, shortly after which the electric lamps began to glow, and in about one minute the entire chamber was most brilliantly illumined, many members being able to read their papers and notes with a distinctness and clearness never before experienced. There was but one opinion expressed, and that was to the effect that Edison's light was a complete success, the only unsettled point being that of cost. The chamber was prepared for this lighting in a very few days with fittings Major Flood Page brought with him from England." The *Argus* of the same date gives a few more details, from which it appears that altogether 46 lamps were used. This paper describes the temperature of the house as having been "very much pleasanter than it has ever been in the memory of the oldest frequenter of the House."

ELECTRIC LIGHTING IN STOCKPORT.—Messrs. Faulder, of Stockport, have lighted part of their premises by means of five Pilsen arc lamps, the current being supplied by an A Gramme dynamo machine, driven by a three horse-power engine. A member of the firm has given an estimate of what it costs him to light his shop by this means, and calculates it at 1d. per hour per lamp. This he states to be about the same price that he originally gave for gas. With the electric lights, however, he gets more light for his money. We leave all the responsibility of these figures with Messrs. Faulder. The lamps were erected by Messrs. Emerson and Murgatroyd, of Stockport, whose electrician has kindly sent us some tests he made after starting the machine and lamps, which he thinks may be of interest, seeing that it is unusual to work Pilsen lamps from Gramme machines. The data he sends us are as follow:—A^2 Gramme machine; resistance of field magnets, 4·3 ohms; resistance of bobbin, 2·4 ohms (brush to brush); speed of machine, 1,600 revolutions; E.M.F. of five lamps, 233·1 volts; ditto of machine, 37·8 volts, or a total E.M.F. of 270·9; current, nine amperes; horse-power, 3·26.

THE EDISON SYSTEM AT BRUNN.—On the 4th inst. some of the actors of the Brunn Theatre, which is lighted by the

Digitized by Google

Edison system, were conducted over the machine room by Mr. Francis Jehl, who carried out the work there. The party included Herr Hans Christian and Fraulein Gollinger and others. Mr. Jehl explained to them the whole process, beginning with the conversion of the coal into heat and the water into steam, how the motion of the engine was communicated to the dynamo machine, and the rotation of the armature before the field magnets produced the current. The principle of the arc light was explained by connecting two carbon pencils to the terminals of the machine, as also was that of the incandescent light. Lamps on the latter system were connected up in series and multiple arc, and the peculiarities of each method explained. The whole of Edison's system was then practically exhibited in detail and explained. It was shown how the current would heat wires, and how power could be transmitted by its agency. Lastly, some paper was soaked in potassium ferricyanide and connected with the current; it was then written upon by an iron pencil, causing decomposition of the salt, and producing a blue mark. This was much appreciated by the lady present, Fraulein Gollinger, who styled it "writing with electricity." Altogether the actors passed an interesting two hours, thanks to the kindness of Mr. Jehl.

Electric Lighting and the Ladies.—At a fancy dress ball, held at Hull recently, a lady somewhat electrified the remainder of the company by appearing with incandescent lamps arranged about her person. To quote a local contemporary:—"Small incandescent lamps were artistically introduced into the head-dress and other portions of the costume, and the electricity was supplied by a gentleman who was in attendance with a box representing a hand organ, from which were wires attached to the lamps." According to this extract it seems a matter of conjecture as to whether the source of the electricity was the gentleman in attendance or the box representing a hand organ. The fact of the matter is that the box was a bichromate battery, which, together with the lamps and fittings, had been supplied by Mr. T. Muse, an electrician of Hull. Now that "A.I.C.E." and *The Times* have discovered the somewhat careless manner in which they "rushed in" to support the claims of the lowly "super" [Should it not be superess?], whose life they discovered to be in danger at the hands of energetic and unscrupulous theatrical managers, no doubt many of the fair sex will follow the example set them at the Savoy Theatre, and again at Hull, and place electricity in the same category as rouge, pearl powder, eyebrow brushes *et hoc genus omne*. We only hope, for the sake of the ladies, that this "novelty" will not be found to have been in vogue amongst the Chinese a few thousand years ago.

"The Advance of Electricity."—This was the title of a popular lecture, delivered by a popular lecturer—Mr. W. H. Preece, F.R.S.—at Basingstoke, a day or two since. Mr. Preece, having made his audience familiar with the theoretical explanation of matter and energy, told them that electricity was usually held to be "a form of that power called energy." Passing from this, Mr. Preece alluded to electricity as the agency by which we worked telegraphs, dynamo-machines, &c. The power of electro-magnets was well illustrated by a large one being made to lift "a heavy poker, with a boy suspended," when the current was passing, whereas it was shown that it would not lift a nail when the current was disconnected from it. The rapid growth of telegraphy, the telephone, storage batteries, the use of electricity for fire alarm and railway signal purposes, the transmission of power, &c., were all brought before the audience in turn, in Mr. Preece's usual happy style. Very many experiments were carried out on the platform to illustrate the subjects referred to, the lecturer having at his disposal numerous dynamo machines, electric lamps, secondary batteries, and other apparatus. The room was lighted by Edison lamps, the current for which was supplied by two Edison dynamos driven by a Wallis and Steevens 6 h.-p. engine. Some Swan lamps and a Pilsen arc lamp were also shown, the current being supplied by accumulators lent by the Electrical Power Storage Company, of Great Winchester-street, E.C. Mr. Preece also acknowledged his indebtedness to the London and South Western Railway Company's telegraph department, and to Mr. Cooper, of the General Post Office.

Electric Lighting in London.—The Vestry of St. James's (Westminster) have adopted a report from their Electric Lighting Committee, in which it is recommended that the Metropolitan Board of Works be informed that the vestry have passed a resolution to apply for a license under the Electric Lighting Act, 1882, and, therefore, object to any provisional order being granted for an area of supply, including the whole or any part of the parish of St. James at present; but that, if the Board of Trade determine to consider the applications of the Metropolitan (Brush) Electric Light and Power Company and the Edison's Electric Light Company, the vestry submit that any draft order that may be granted should (1) take the whole parish as the area of supply; (2) provide for a continuous supply of electricity; (3) contain a provision for reducing the charges for electricity, if cost of production or distribution is lessened, or the company earn more than 10 per cent. net profit per annum; (4) the period for purchase by the local authority should be reduced to 14 years; (5) adequate safeguards should be introduced by the Board of Trade to ensure the company fulfilling their obligations.—Mr. H. L. Isaacs, surveyor to the District Board of Works for Holborn, has reported to the board that at the present moment it is not desirable that they should apply for a license or provisional order to enable them to supply electricity for lighting purposes, and he thinks that very great care will have to be exercised that, whilst avoiding on the one hand the grant of an absolute monopoly to any one of the competing electric light companies, the most stringent conditions are imposed on the companies to prevent the streets and roads from being ruthlessly interfered with, as would be the case when rival companies were empowered to serve the same district.—The Poplar District Board of Works will not apply for an order or a license, but will wait and see what private enterprise will do for them before they move in the matter.

Our Obituary for 1882.—During the past year we have had to chronicle the following losses which electrical science and applied electricity have sustained at the hand of death. Taking the names in alphabetical order we come first to (1.) Thomas B. Ascough, of the Postal Telegraph Department. He was originally connected with the Universal Private Telegraph Company. (2.) Antoine Breguet, the well-known French electrician. (3.) Professor Henry Draper, a distinguished scientist of New York. (4.) A. J. Hare, superintendent of the Eastern Extension Telegraph Company's station at Madras. (5.) Charles Hockin, a member of the firm of Clarke, Forde, and Co., telegraph engineers, and well known in connection with cable laying, and the British Association Unite Committee. (6.) T. W. Keats, consulting chemist to the Metropolitan Board of Works, who is also known as the author of a report on the Jablochkoff system of electric lighting. (7.) Joseph Christopher Laws, who was connected with the laying of the first Atlantic cable in 1858, and latterly occupied the position of head of the

Digitized by Google

electrical staff at the works of the Telegraph Construction and Maintenance Company, with whom he had been connected since 1869. (8.) George Leclanché, of Paris, known all over the world as the inventor of the Leclanché battery. (9.) Joseph Liouville, a celebrated French mathematician, who also wrote on electrical science. (10.) General von Lüders, director-general of Russian telegraphs for more than fifteen years, and better known to English telegraphists in connection with the Telegraph Conference held in St. Petersburg in 1875. (11.) Thomas H. Sanger, divisional-engineer of the Telegraph Department of the General Post Office in Ireland. (12.) Carl Louis Schwendler, a native of Prussia, for some time in the employ of Messrs. Siemens and Halske, by whom he was engaged in laying several cables. He was subsequently appointed to a high position in the Indian Telegraph service. He is well known as the author of one of the best books on electrical testing that has ever been published. (13.) C. V. Walker, F.R.S., telegraphic engineer to the South Eastern Railway Company, the translator into English of De La Rive's celebrated work, the assistant of Mr. Cooke in the erection of his first telegraph wire, and the layer of the first submarine cable. He also patented many practical applications of electricity.

Improved Galvanic Battery.—The *Scientific American* illustrates and describes a battery patented by a Mr. Parkhurst in a recent number. Our contemporary says:—"In this galvanic battery the positive plate is made of zinc, in any of the well-known shapes, and is provided with a wire conductor connected with it in the ordinary way. The negative plate, which is of carbon, is placed in a porous cell and surrounded with a mixture of granulated gas retort carbon, granulated black oxide of manganese, and mild chloride of mercury, or calomel, equal parts. These materials are intimately mixed together with a small quantity of water before being placed around the negative plate. As the fluids of this battery, when in operation, are very corrosive, the upper end of the carbon is saturated with paraffin or wax, and the electrical connection is made with it by casting lead or solder around it, and attaching to it a binding screw. The porous cell is filled around the carbon to within a short distance of the top of the cell with the mixture of gas carbon, black oxide of manganese, and chloride of mercury, and the top of the cell is sealed with a cement of resin and wax, or any other insulating cement insoluble in the fluid of the battery. Two small holes are left in the cement for the admission of water or the exciting fluid, or for the escape of gas which may be generated in the porous cell. The porous cell, containing the carbon plate, the granulated carbon, and black oxide of manganese, and the chloride of mercury, as above described, is placed in a suitable jar, together with a zinc rod or plate which has been amalgamated. The exciting fluid is a saturated solution of ammonium chloride or sal ammoniac. The action of this battery is as follows:—The zinc, calomel, carbon, and manganese being all insoluble in water, there is no internal action when the circuit is open. The circuit being closed, decomposition commences. The zinc is oxidised by the water of the sal ammoniac solution forming oxide. This zinc oxide immediately reacts with the sal ammoniac (ammonium chloride), first combining with a portion of the chlorine of the latter (and displacing an equivalent of ammonia), and then combining with another portion of the sal ammoniac, forming ammonia zinc chloride, while the ammoniac becomes converted into ammonia. The hydrogen being liberated at the negative plate, unites with its equivalent of oxygen from the peroxide of manganese, reducing this to the sesquioxide, and by this union forming water. The ammonia reduces the calomel into metallic mercury and hydrochloric acid, which latter unites with the ammonia, forming ammonium chloride, to be decomposed, as above described, or this latter acid may act directly upon the zinc, thereby intensifying the action of the battery."

Electric Lighting at Berechurch Hall.—Mr. O. E. Coope, M.P., writes to *The Times* of Tuesday last, giving details of the cost of lighting his residence at Berechurch Hall by incandescence lamps. From this letter we make the following extracts:—"I engaged the services of Mr. Heaphy, C.E., of the Phœnix Fire Office, to advise me upon the matter and superintend the installation on my behalf. We examined together every different system of lighting, the result being that I determined to adopt the Swan incandescent light and the Bürgin machine, and accepted the tender of Messrs. Crompton and Co. to supply the same, after I had instructed Mr. Heaphy to draw up a regular specification and contract going into every detail, and giving me the power of rejecting any work or materials he was not perfectly satisfied with. We arranged to have 200 lights of 18 candle-power each, and four dynamo machines; the engine to be of 12 horse-power, with very sensitive governor and with tubular boiler, all leads and wires to be heavily insulated in the best possible manner, and the insulation to be rendered non-inflammable inside the rooms. They were to be embedded in the walls, and kept at least 4in. apart from each other, and 4in. from every kind of metallic substance. Every floor, every room, and, in many cases, each light to have switches to turn the current on and off, as well as a lead 'cut out' to guard against overheating of the wires. The whole has been carried out as specified, and the result has been a success that has exceeded my expectations. I will now give details as to cost:—Estimate for gas plant, buildings, and erection, £740; gas main to house, £75; laying pipes in house, £200; cutting and making good again, £50; chandeliers and brackets, &c., £268 18s.—total, £1,333 18s. Cost of electric light:—Four dynamo machines, £405; 220 Swan lamps, £55; 200 sockets for same, £10; cable, wires, switches, and cut outs, £66 4s.; cutting and making good walls and floors and incidental work, £60; engine and boiler, extra fly-wheel and belting, £300 6s.; counter shafting, £25; foundations to engine and flooring, £40; erection, laying wires, &c., and carriage, £90; buildings, £150; chandeliers and brackets, &c., £268 18s.—total, £1,470 8s. I will now estimate the annual working expenses, and, in making a comparison, I will assume that it would cost the same to manufacture 1,000 cubic feet of gas at Berechurch as it does here. Electric light—200 18-candle lamps, each working 1,150 hours per annum.—Coal at 20s. per ton, £38 10s. 1d.; engine driver at 30s. per week, £78; renewal of lamps, 153 at 5s. each, £38 5s.; depreciation 10 per cent. on cost of machinery, £74; depreciation 5 per cent. on conductors, £4. Total, £232 15s. 1d. Now, for less than half this amount of light it costs me £200 a year here (Rochetts, Brentwood), and, therefore, I am, if anything, understating the expense when I say that, had I used gas at Berechurch giving an equivalent illuminating power, it would have cost me at least £400 per annum to produce. This would show an annual saving of £167 4s. 11d. to me by using electricity. Having had twenty years' experience of lighting this house by gas—which I consider a great improvement upon any previously known method—I am only too sensible of its drawbacks, and, although I am not doing away with it here yet, I am well satisfied that I have adopted electricity at Berechurch." We may remind our readers that we described and illustrated this installation in our issue of December 2.

THE EARTH A GREAT MAGNET.—This was the title of a lecture delivered by Professor Silvanus P. Thompson at Glasgow a few days ago, under the auspices of the Glasgow Science Lecture Association. Sir William Collins presided, and amongst other scientific gentlemen present was Sir William Thomson. Professor Thompson traced the history of magnetism from the time of Dr. Wm. Gilbert, one of the physicians of Queen Elizabeth, by whom it was raised from the region of superstition and fable to that of true science, remarking that in Gilbert's book he had found the title of his address, "The Earth a Great Magnet." He proceeded to show, by experiment, the properties of the loadstone, of the magnet, and of the mariner's compass, and pointed out the various modes in which a magnet might be formed. He illustrated the declination of the magnetic needle, and explained the difference between the magnetic and geographical poles. The magnetic pole, he stated, was at present near Boothia Felix, more than a thousand miles to the west of the geographical pole. In 1657 the position of the needle showed the magnetic pole to be due north. It had been eastward before that. It then began to point westward, and the westward variation increased till 1816, when the maximum was attained. It had since steadily diminished, and in 1976 it would again point to the true north. The changes which had been observed, not only in the direction, but in the strength of the earth's magnetism, showed that the same causes which originally magnetised the earth were still at work. Strangely enough these changes did not occur at long intervals in the course of centuries, but were going on from day to day, from week to week, and from year to year. This was illustrated by those magnetic storms which interrupted telegraph operations, rang telephones, and, as was reported lately, kept one of Edison's lamps alight, though he would have liked to have seen it. These magnetic storms were most frequent in the month of May and fewest in June, again reaching their maximum about October. It had also been observed that the more violent the magnetic storms the more numerous were the spots on the sun, and the more brilliant were the auroral displays around the poles. The phenomena of the aurora were among the mysteries of science of which no explanation had been given; but it was certain that the aurora was an electrical discharge passing from the equatorial regions through the upper air, and descending at the poles, where a condensation of vapour was continually taking place. The earth was thus continually surrounded by electricity, and here, he thought, was to be found the answer to the question how did the earth become a magnet. That it was not always a magnet he regarded as certain, seeing that there were good geological grounds for believing that it was once a molten mass, and that nothing destroyed magnetism like heat. Faraday had found that by taking a bar of iron, spinning it on its axis, and carrying a current of electricity round it from the centre to the poles, a magnet was formed. As therefore there was a current of electricity continually flowing from the equatorial regions to the poles and returning again to the equator, he put forward as a guess that in this way the earth revolving continually on its axis had been converted into a magnet. This theory, of course, involved that the magnetism of the earth had been growing, was growing, and would continue to grow.

THE SEPARATION OF METALS BY ELECTROLYSIS.—This is an abstract of a paper by V. Francken, which appeared in the *Chemical News*, and relates to the processes of Claesson and Reis. The abstract, as under, is taken from the December number of the *Journal* of the Chemical Society:—"To obtain accurate results the methods recommended must be carried out most exactly. For the determination of cobalt an excess of neutral potassium oxalate must be added, but as the oxalate is gradually decomposed by the current, cobalt carbonate is deposited with the metal; this precipitate must be removed by cautious addition of oxalic or sulphuric acid. The deposition of the metal is, however, more rapid if ammonium oxalate replaces the potassium salt, but no more should be added than is necessary to form the soluble double salt. There is deposited with the metal a red insoluble oxide which is but slowly reduced; to prevent this, the liquid to which an excess of oxalate has been added is heated, and a further addition of 3—4 grams of solid salt is made. The cobalt forms a grey adhesive coating, which must be well washed with water, alcohol, and ether, and then dried at 100 degrees. Nickel is estimated in a similar manner. In the determination of iron, the chloride or sulphate, with excess of ammonium oxalate, may be used, and in the reduced state it does not readily oxidise. Zinc, separated as above, adheres firmly to the electrode, and cannot be removed by dilute acids, but can be detached by heating the capsule to redness, and treating the residue with fresh acid. The precipitation of manganese is complete only when but little nitric acid is used; the presence of potassium oxalate causes separation of the peroxide, and this oxide is not firmly attached to the electrode, so that it must be separated by filtration, and converted by heat into $Mn_3 O_4$. Ammonium oxalate must be added to bismuth nitrate solution, but some peroxide is formed which is but slowly reduced; great care in removing all water by alcohol and ether must be exercised, so as to prevent oxidation. The electrolytic deposition of lead cannot be recommended. Copper separates from an ammonium oxalate solution with great ease and accuracy. Cadmium forms a grey coating, which, although not adhering firmly, can be removed without loss if washed cautiously. Tin separates from the solution of chloride or oxalate as a fine grey coating, antimony separates as a fine light grey firmly adhering precipitate from solutions to which sulphuretted hydrogen has been added. If the solution be acid, ammonia, or ammonium sulphide in excess, is added. Ammonium sulphate accelerates the reduction. Arsenic cannot be separated quantitatively. Iron and manganese can only be separated if the formation of the manganese peroxide is prevented until the greater part of the iron has been precipitated. The presence of ammonium oxalate affects this result. If the oxalate has been decomposed before the end of the precipitation, and this is shown by the formation of a pink colour, heat must be applied, and three to four grams of oxalate added. If the quantity of manganese is small, it appears as peroxide at the positive electrode, but if the proportion of manganese is double that of the iron, then the peroxide must be dissolved in oxalic acid, without interruption of the current, so as to effect complete separation. The precipitation of manganese from the solution of oxalate as peroxide is not quantitative, therefore the liquid holding the greater part of the manganese peroxide in suspension must be boiled so as to decompose the ammonium carbonate, and then neutralised with nitric acid, after which the metal must be precipitated as sulphide. Iron and alumina are separated so long as the ammonium oxalate is in excess of the carbonate formed by electrolysis; as in the previous cases an excess of oxalate (three grams per 0·1 gram oxide) is added to the solution of the double oxalates, and the mixture is electrolysed whilst hot. If the alumina is in excess of the iron, the same precautions must be taken as in the case of manganese."

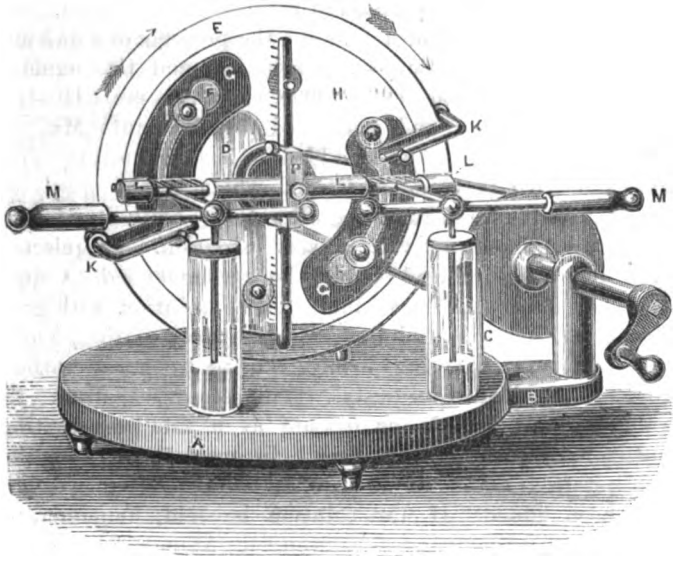
THE VOSS INDUCTION MACHINE.

BY J. T. SPRAGUE.

This machine unites great simplicity of construction with high efficiency, generating high tension electricity with less expenditure of power than other machines. It is claimed that its action is independent of atmospheric conditions, but my own experience is that while not so much affected by damp air as most others, it requires a dry air to work satisfactorily. The figure shows a very simple construction, which generates four-inch sparks at a sufficient rate to illuminate vacuum tubes steadily, and to maintain the appearance of a continuous stream of fire.

The base A carries a sliding bar, B, on which the driving wheel is mounted, so that the tension of the driving cord is easily controlled. The fixed plate of thin glass E is 12½in. in diameter, with a central opening of 3in., and has fixed upon its further side two pairs of tin foil discs connected by a strip of foil. These discs F F are covered by paper shields G G, which serve as collectors from the surface of glass covered by them. This plate, which forms the field or inductive system analogous to the field magnets of dynamo machines, is supported by two ebonite studs upon the base, and an ebonite rod entering into the central opening. This rod is fixed into a wooden pillar D, firmly secured to the



base, and a little below it is fixed a conical axis which carries the moving system and the collectors. The moving plate H, which answers to the armature of the dynamo machine, is of 10¼in. diameter, and at six equidistant points of a circle of 7½in. diameter are fixed inch discs of foil, upon the middle of each of which there is cemented a metal button, rising ⅛in. from the surface. These discs *i i* correspond to those of the fixed plate. The plate is mounted upon a tube, by means of an ebonite flanged screw and nut. The tube carries a driving pulley at the other end, and is bored to fit the axis, and secured upon it in place by a broad brass nut, screwed on the axis, which projects further to carry the collecting system. This consists of an ebonite rod, L, which is held horizontal by means of the axis, and two steel pins on the face of the nut. At each end is a brass T piece, carrying a collecting comb, and on the other arm a ball, which carries the discharging rod M, and is supported by a small Leyden jar, N. These two jars are connected together at the outer coatings by the metal saucers, which are united by a wire on the lower side of the base. I think this arrangement is open to improvement by supporting the arms with insulating pillars, and insulating the jars. In fact, one jar, with its coatings connected to the arms, would be sufficient in that case. As it is the jars make "earth" at the middle of the scale of potential of the machine, which is undesirable for many purposes.

The whole of the glass surfaces should be warmed and carefully varnished, so as to resist the deposit of moisture; and, when worked, all dust should be removed.

A second pair of combs, shown vertical, are attached to a brass frame, P, also placed on the axis, and secured there by a knob of ebonite screwed upon the end. These combs have fine wire brushes in their middles, which touch the buttons and short circuit the discs so as to discharge them just as they leave the paper shields, over the ends of which this zero comb should be placed. K K are bent arms of metal, attached by clamps to the fixed plate, and connected by strips of foil to the nearest foil disc. These arms carry fine metal brushes, which are adjusted to touch the buttons on the moving plate at the instant they face the foils on the fixed plate, so as to close a circuit at that moment, and enable the mutual reactions and accumulations to take place. As in dynamo machines, there is always some trace of residual charge, and successive inductions and transfers accumulate this, till the limit of the machine is reached, when the electricity flows into the external circuit, accumulating in the jars, and giving off in sparks proportioned to the space between the discharging balls.

The only defect of the machine is a tendency to self-reversal, which is apt to occur at a stoppage. It can be produced when desired by holding a metal point to the + brush K. The two derived inductive circuits are beautifully manifested when this machine is worked in the dark. A stream of fire is seen pouring towards the collecting comb L, on whichever side of the machine is +. If the discharging balls are set near to each other, so as to reduce the resistance of the external circuit to a minimum, this light at the + collecting comb is very brilliant; but as the balls are drawn further apart, the light there diminishes, and is transferred to the comb on the zero pair P.

I have connected the machine to a delicate galvanometer, by means of a third discharging ball, and I found when the balls were in contact, a current was generated of ampere ·00004 (50deg.). With opening of a quarter inch the current instantly fell to 10deg. (ampere ·00005). But as this interval was increased the deflection increased also, and when it became too great for sparks, and only a hissing discharge occurred, the deflection had risen to 45deg. I found the current developed was regularly proportioned to the rate of rotation, but how far this is due to variation of E.M.F. or of resistance, I had not the means of ascertaining. I also found that my observations as to current were useless as to endeavouring to make them accurate, because my galvanometer was deflected with only one terminal connected; either through the "earth" connection referred to, or else by direct induction, a circuit is completed whether it is desired or not. But my galvanometer was not intended for such treatment, having been made with a series of exchangeable coils for use with the Wheatstone bridge. The coil in use was one of 350 ohms resistance.

The machine produces beautiful brush and star discharges when the − ball is removed; if the + ball is removed there is no brush, but a violet star on the point. Ozone is freely produced while working.

An interesting experiment is to open the discharger balls about 2in., and tie a piece of soft thread across loosely; the thread is at once attracted up close to the balls, then strong attraction for the opposite portions draws the thread tightly up and instantly forms the loose parts into a loop which stands over the thread, occasionally approaching the + ball. If the loop is loose enough, it will be drawn out into an ellipse. With this thread sparks will pass over a distance which would prevent discharge without it. If the thread is cut across the middle its ends draw up and cling together long after the working is stopped.

I took the opportunity of testing the action on flame, as to which Mr. Johnstone wrote so strongly some time since, with results, as I expected, very different from his. I used a benzoline sponge lamp made of metal and stood between the balls. Of course, the flame tended towards the − ball, as though blown over from the +, while the lamp was insulated, but, if a connection was made to it from either pole, the flame was attracted to the other pole, provided the machine were worked gently. But this is overcome by a very singular

Digitized by Google

phenomenon when the motion is increased. When the lamp is connected to +, the flame pours down the stem in a regular bubbling cascade, while the supply of spirit increases largely, and very soon the light is fairly carried away from the wick, and goes out. I purpose examining this action with appliances adapted to the purpose as soon as I have leisure.

CURRENT ENERGY.—I.

BY OLIVER HEAVISIDE.

As we remarked towards the close of Art. III. ("Magnetic Force and Current," p. 177 *ante*), if we adopt Ampère's theory of magnetism, and substitute for every magnetised particle a closed current flowing round it, we may do away with free magnetism, or imaginary magnetic matter, and have nothing but electric currents to deal with. It is, indeed, not necessary to introduce magnetism at all. We did that in order to reach the definition of a unit current in the electro-magnetic system, which is based upon that of a unit magnetic pole. We might, for example, obtain an equivalent result from the mechanical force between the terminations of two long solenoids, which varies inversely as the square of the distance, or in various other ways.

We found that the magnetic force of a small plane closed current could be derived from a scalar potential, that the force was what would be produced by equal quantities of positive and negative matter very close together, in fact supposed to be indefinitely near each other, the quantity of matter being at the same time indefinitely great, but so that the product of the quantity into the distance was finite. If magnets were unknown, this matter would be certainly purely imaginary, quite as much so as the matter which, quite similarly, would give rise to a scalar potential, whose derivatives would express the vector-potential of electric currents in space where there was no magnetic force, or, to come nearer home, the matter whose potential derivatives express the electric force wherever it has no curl, which last matter is the imaginary matter of free electricity. The fact that magnets exist does not make the magnetism any the more real, considered merely as a self-repulsive substance existing wholly on the surface of a solenoidal magnet, and also within its substance when not solenoidal; and the same may be said of the electricity once supposed to reside upon the surface of conductors.

But it happens to be a considerable assistance to make use of the idea of magnetism (or of magnetic polarisation, which comes to the same thing) in reasoning regarding electric currents, and it is particularly useful when we are considering the energy of currents. In fact, it would certainly be employed for this purpose were magnetisation unknown (presuming that this would not involve the non-existence of current) in the form of a magnetic shell, for the idea presents itself in a perfectly natural manner.

Suppose we have a current circulating in a closed path of any form, which we may, when we do not want to go into the space occupied by the current, regard simply as a closed curve. Such a current is a linear closed current. Let C be the strength of current. If we join any two points of the circuit by means of another line, and let the same current C go both up it and down it at the same time, we form two closed circuits both with equal currents of strength, C flowing round them, with the same direction of rotation as regards lines drawn through the original closed curve, which lines we may reckon to be positively directed when the current flows round them righthandedly. Now, since the two circuits have a portion of their length in common, in which equal currents are oppositely directed, there can be no change in the magnetic action at all; hence, the two closed currents, when taken together, are exactly equivalent to the original one.

Therefore, by the same reasoning as was employed in the demonstration of Theorem II., p. 56, if we suppose the original circuit to be the boundary of a surface S, and we divide this surface into an indefinitely great number of small elements of area dS, and let the same current C flow round the boundary of every one of those elements with the same direction of rotation, we know that the whole collection of small closed currents produces identically the same field of magnetic force as the single current C flowing round the boundary of the whole. The form of the surface is quite indifferent; the essential circumstance is that it must be bounded by the real current.

Now, we found (see p. 177) that the magnetic force of a current C circulating round the boundary of a small area dS was the same as that due to charges of magnetism of amounts $m\,d$S and $-m\,d$S placed on opposite sides of dS at the small distance dz apart, the axis of z being that of the current; that is to say, z is the normal to dS. The condition connecting m and C is that $m\,dz = $ C, or magnetic moment of magnet = that of the current (per unit of area, here).

Let the surface of every one of the small-closed circuits we have imagined to replace the real circuit be similarly covered with magnetism on its two faces, according to the same rule. This is equivalent to covering the complete surface S to surface density m on one side and $-m$ on the other, with the condition $m\,dz = $ C everywhere; $m\,dz$, the magnetic moment per unit area, is called the Strength of the shell. The thickness of the shell must be indefinitely little, but it need not be constant. If it vary, m must vary inversely, so as to keep the strength constantly = C. The magnetic force of this shell and that of a current C round its edge are identical everywhere, except in the shell itself.

Now, since the mechanical action between a magnet and a small closed current is the same as that between the magnet and a small magnet of the same moment as the current, similarly placed, and since we may build up any closed linear current by putting together an immense number of such little closed currents, it follows that the mechanical action between a magnet and any linear current is the same as that between the magnet and an equivalent magnetic shell. But the magnet may itself be a second magnetic shell, and since we may substitute for it a current round its edge, it follows that the mechanical action between two closed currents is the same as that between two magnetic shells whose edges are bounded by the currents, and of numerically the same strength as the latter. And the mutual potential energy of the two currents must be the same as that of the shells, which may be found from the distribution of the magnetic matter.

Now, we found (p. 177) the magnetic potential of an element dS of a shell of strength C to be $\Omega = -\mathrm{C}\,d\mathrm{S}\,\frac{dr^{-1}}{dz}$ (now employing the common definition of unit pole), where r is the vector drawn from dS to the point Q where Ω is measured, and z the normal to dS. The differentiation in the above is performed at Q. If we perform it at dS, we must write $\Omega = +\mathrm{C}\,d\mathrm{S}\,\frac{dr^{-1}}{dz}$; because if $\frac{1}{r}$ decreases when dS is fixed and Q is shifted in direction z, it increases when Q is fixed and dS shifted in the same direction.

Place a magnetic pole of strength C at the point Q. Its potential at dS is $\frac{\mathrm{C}}{r}$, therefore its force at dS in the direction z is $-\mathrm{C}\frac{dr^{-1}}{dz}$, and since z is normal to dS the whole amount of force passing through dS from its $-$ to its $+$ side, due to the pole C at Q, is $-\mathrm{C}\frac{dr^{-1}}{dz}d\mathrm{S}$, the differentiation being performed at dS. But this, with sign changed, is our expression for Ω, the magnetic potential at Q of the element of the shell at dS. The same applies to every element of the shell; consequently, by summation, it follows that the magnetic potential Ω at Q of the complete shell = amount of force passing through the shell in the positive direction, due to a pole of strength $-$ C placed at Q, or in the negative direction if of strength + C. Thus, we may express Ω in terms of a solid angle, as for electric force at p. 55; thus, Ω at Q = C × solid angle subtended at Q by the edge of the shell. The magnetic potential of a current C round the edge of the shell is of course the same.

Digitized by Google

The magnetic potential Ω must not be confounded with the vector-potential A. The curl of the latter gives the magnetic force everywhere, both within and without a current; whereas Ω is scalar, and the magnetic force $= -\nabla\Omega$, where ∇ has the same meaning as at p. 152, and this only in space where there is no current. Therefore, in currentless space only, $B = \text{curl}\, A = -\nabla\Omega$; otherwise, $B = \text{curl}\, A$, and Ω is non-existent.

Next, consider two shells of strength C_1 and C_2, and let Ω_1 and Ω_2 be their magnetic potentials. The mechanical force between them may be ascribed to the mutual actions of the magnetic matter, and calculated therefrom. To fix ideas, let the shells be circular planes. If we place them parallel to one another, upon the same axis, and so that the N. side of one is next the S. side of the other, there is attraction between them. We may call the N. face of a shell the + face, and the S. the − (N. and S. meaning north-seeking and south-seeking, as applied to a needle), so that the N. face of shell is the same as the + face of the corresponding current round its edge. The + direction through the shell or the current is from the − to the + face. The magnetic force of a closed current goes through it in the + direction; it also goes right-handedly about the current, and the current goes right-handedly about a line of force. These relations, which are sometimes puzzling to others besides beginners, are important to be remembered, for confusion will inevitably arise if we do not keep to one consistent system. In our present case the parallel shells with contrary faces next each other attract. The corresponding currents round their edges are similarly directed, so there is consistency with the fact that parallel currents attract or repel according as their directions are similar or opposed.

Since we (temporarily) ascribe the force between the shells to the attraction of matter, their mutual energy is, on this view, potential energy, and tends to decrease. If one shell be fixed, and the other move through a distance dz parallel to itself, and F be the mechanical force in the direction of motion, the work done by the force is $F\,dz$. This is also the reduction in the amount of potential energy; or $-dM$, if M be the mutual energy. Therefore, $F = -\frac{dM}{dz}$ is the expression for the force. This is, in the case considered, a real force in the dynamical sense, viz., acceleration of momentum. But we may give an extended meaning to the term force (and this is important in the theory of energy). Let dz indicate *any* displacement, and $-dM$ the corresponding fall in the potential energy, then $F = -\frac{dM}{dz}$ is the "force" in the generalised sense, so that "force" × displacement always equals the decrease of potential energy during the displacement.

The two shells with contrary faces nearest, would attract each other from an infinite distance, and their potential energy would decrease all the time; hence, if the energy be taken = 0 at an infinite distance, where the force is evanescent, the energy is negative at any finite distance, and becomes more and more negative as the shells approach. Turn one of them round, so that similar faces are nearest; the potential energy is now positive, the amount of work done in turning the shell round being the whole increase of energy. (Rigid magnetisation supposed.) Similar remarks apply to the currents round the edges of the shells, but we have not under consideration at present what becomes of energy added to the system by externally performed work.

The mutual energy of two shells or currents admits of tolerably simple expression by means of the theorem connecting line and surface integrals. If a charge m of magnetism be brought from an infinite distance to a place in a magnetic field where the potential is Ω, the work done against the repulsion is $m\Omega$, which is consequently the potential energy of m with respect to the field in which it is placed.

Apply this to a shell placed in the field of a second shell. Let dS be an element of area of the first shell, of strength C, and dz its thickness, z being, therefore, the normal at dS. On the + face there is magnetism to the amount $m\,dS = \frac{C}{dz}\,dS$. Let Ω' be the magnetic potential of the second shell there. The energy of $m\,dS$ with respect to the second shell is then $\frac{C}{dz}\Omega'\,dS$. Now, Ω' becomes $\Omega' - \frac{d\Omega'}{dz}\,dz$ when we pass through dS to the other side, where there is a quantity $-\frac{C}{dz}\,dS$ of magnetism, whose energy with respect to the second shell is, therefore, $-\frac{C}{dz}\,dS\left(\Omega' - \frac{d\Omega'}{dz}\,dz\right)$. The energy of the combination is the sum of the separate energies of the two charges of magnetism, that is, $C\,dS\,\frac{d\Omega'}{dz}$.

But $\frac{d\Omega'}{dz}$ is the magnetic force at dS of the second shell in the direction of the normal from the positive to the negative side; therefore, $dS\,\frac{d\Omega'}{dz}$ is the amount of magnetic force arising from the second shell which passes through dS in the negative direction. The same is true for all areas in the first shell; hence, by summing up, we find that the energy of the first shell with respect to the second = strength of first shell × total amount of magnetic force passing through it in the negative direction arising from the second shell. Or, if M denote the energy, and we always reckon the force in the + direction through a shell,

$M = -C \times$ amount of mag. force through C due to C′. (1),

if C′ is the strength of the second shell. Similarly, by starting with the second shell, we find

$M = -C' \times$ amount of force through C′ due to C . (2).

[It is customary to speak of the "number of lines" of force, each line being the representative of a definite "amount" of force, or "surface-integral" of force, to use the mathematical expression. But no-one speaks of the "number of lines" of current passing through a surface; the expression "amount" or "quantity" would be rather used. Fractional parts of a line of force are awkward, but there is no such difficulty with amount or quantity. On the other hand, "surface-integral" is rather too scientific.]

The right hand members of equations (1) and (2) are identically equal, and a remarkable reciprocal property of closed currents or shells is disclosed. Make the currents each unity; then it follows that the unit current in the first circuit sends the same amount of force through the second as the unit current in the second circuit sends through the first, whatever may be the form or relative position of the circuits.

Equation (1) does not apply merely to the field of a shell or single circuit. By the manner of its derivation it applies to any magnetic field whatsoever produced by magnets or currents, substituting for "due to C′" the expression "due to the field." This is to exclude the magnetic force of the current C itself.

Equations (1) and (2) may be immediately put in another form. The magnetic force of a current is the curl of its vector-potential, therefore (by Theorem II., p. 56) the amount of magnetic force through any circuit = line-integral once round it of the vector-potential, whose curl is the force considered. So let A and A′ be the vector-potentials of C and C′, then (1) and (2) become

$M = -C' \times$ line-integral of A once round C′ . . (3)

$= -C \times$ line-integral of A′ once round C . . (4)

These, again, may be put in another form, which will be useful. Consider (3) only. Let ds' be an element of length of the current C′. The portion of M due to it alone is $-A\,C'\,ds'\cos(A\,C')$, or simply $-\overline{AC'}\,ds'$, (if we place a stroke over the product of two vector quantities to signify that the product of their magnitudes (disregarding directions) is to be multiplied by the cosine of the angle between their directions, *i.e.*, A multiplied by component of C′ along A, or C′ multiplied by component of A along C′; as will be done hereafter). But A is itself a line-integral, viz., once round the current C. Let ds be an element of length of C, then the portion of A contributed by it is (by

Digitized by Google

the definition of vector-potential) $+ \frac{C}{r} ds$ at a point distance r from C, and its direction is parallel to C. Therefore the portion of M due to the pair of elements C ds and C′ ds' is

$$-\frac{1}{r} CC' \cos(CC')\, ds\, ds' \text{ or } -\frac{1}{r} \overline{CC'}\, ds\, ds' \quad . \quad . \quad . \quad . \quad (5)$$

and the complete energy is the sum of all such terms, so as to include the whole of both currents, *i.e.*,

$$M = -CC' \iint \frac{\cos \epsilon}{r} ds\, ds' \quad . \quad . \quad . \quad (6),$$

where r is the distance between ds and ds' and ϵ the angle between their directions, and the integration extends once round each circuit, the direction chosen being that of the current in each case. (6) is the simplest form of Neumann's formula.

With respect to (5) and (6), the latter, referring as it does to closed circuits, is exact; but as regards the former all we can say at present is that the potential energy of two closed currents is the same *as if* a pair of linear elements, one taken from the first circuit, the other from the second, possessed the mutual energy expressed in (5), for such elements could not exist alone.

ELECTRICAL ACCUMULATORS OR SECONDARY BATTERIES.*

BY PROFESSOR OLIVER LODGE.

No. X.

Having charged the cell and allowed it to stand idle for a time it only remains to discharge it.

The regular and normal operation of discharge would be as follows:—We start with the opposing surfaces—spongy, hydrogenised lead on the one side, and peroxide, more or less saturated with oxygen, on the other—as near together as they can ever be, and with a highly-conducting, strongly acid liquid in the narrow space between. An initial current of great vigour is, therefore, produced, and any spare oxygen is probably at once consumed. The current continues, with hardly diminished intensity, until the surface hydrogen has also disappeared, and a scum of sulphate forms on the negative plate. This is the first thing that causes any serious weakening of the current; only it must be remembered that it acts by increasing the internal resistance, not by diminishing the electromotive force to any important extent, and hence, that it may considerably reduce the strength of a powerful current, although a test with an electrometer or high resistance volt-meter might not show any marked deterioration. The more powerful the current demanded, the more is the resistance offered by this scum of consequence, and, moreover, the sooner does the scum form; and this is mainly why a cell refuses to give a very strong current for many minutes together.

On allowing the cell to stand the scum clears off, and the original power is to a great extent restored. And there is to be noticed about the scum, that the faster it is formed the faster it clears off. If it is formed very rapidly by a very powerful current, the cell need not stand long to recover itself; but if it only forms after a long continuance of a weak current, it is much more permanent, and a long period is necessary for recovery.

The scum always takes longer to clear off than to form, but the two times are not greatly different. The clearing away of the insulating film is due, I believe, to the local action between the hydrogenised lead in the deeper layers of the coating and the dehydrogenised lead of the surface; and if this is so, there must come a time when the film will refuse to clear off, and a permanent increase in the internal resistance will set in, increasing as the action penetrates deeper and deeper into the negative coat until the still metallic lead can only be reached by penetrating through a surface layer of non-conducting matter, consisting mainly of sulphate, but also partly, I think, of the lower oxides of lead.

Messrs. Gladstone and Tribe have made the remarkable observation that patches of *peroxide* form on the — plate during the discharge. The fact has not come under my own notice, as I was so totally unprepared for any such phenomenon that I never looked for it. However, as Messrs. Gladstone and Tribe have detected it by chemical analysis, we must accept the fact, unexpected as it is; and certainly a film of such a substance on the negative plate will account for any amount of falling off of the cell, down to complete stoppage, by reason of its high opposition electromotive force. Moreover, it is certain that local action would speedily clear away such a deposit, and hence, given such a film as this, the loss of power and recuperation of the cell are accounted for in the fullest and most satisfactory manner.

Any difficulty which one feels in perceiving how the peroxide comes to form on the plate during discharge, of course only exists when the cells are discharged separately. When a number of cells are discharged in series, as is common, it is the simplest thing in the world for those which get empty first to begin to charge up in the reverse direction by the current from the others; and the current from a set of cells will therefore cease, not when all are discharged completely, but when the opposition electromotive force of the worst cells becomes equal to the remaining electromotive force of the best. Then allowing the cells to stand a bit, the worst cells will lose rapidly their opposition electromotive force, and accordingly the set will have picked up again and give a residual charge, until the electromotive forces balance again; and so on alternately, the action being precisely analogous in every respect to the residual charge of a Leyden jar with a stratified dielectric, as worked out by Maxwell. But, as Kohlrausch pointed out, to get *Nachwirkung* it is not essential to have a stratified dielectric, so with secondary batteries. A single cell will give it, though not to the same extent as a series.

It is obvious that all these actions are very objectionable, and not at all what is wanted in practice; but as long as cells are not all identical, a series must give these effects in a very marked degree. If it is impossible to make cells really alike, therefore the best plan is to make them as best you can, and then test them and sort them out into qualities, putting all of the same sort together, where they will work much better and more steadily than if mixed with others either better or worse.

A certain percentage will naturally be found exceedingly good; and these, also quite naturally, may be selected for important occasions, such as crossing the Channel.

And now what about the positive plate during discharge. In the normal operation the front layer of peroxide will get reduced to a lower oxide, apparently the yellow oxide litharge, and much of this will be then turned into sulphate by the acid. After this action has gone on for some time the internal resistance of the cell must have increased by reason of the non-conducting layer of lower oxides and of sulphate which intervenes between the active layer of the peroxide and the main body of the liquid.

I apprehend that all reduction of this kind is permanent, and that no recuperative chemical changes go on at this plate when the current is interrupted. Nevertheless, it is a certain fact that the power of the + plate too does fall off temporarily while producing a current and pick up again when standing idle, though not, I think, to the same extent nor so soon as the power of the — plate does; in fact, for a long time the fall and rise is not much noticed, but it is most apparent when the active layer is buried at some depth beneath the clogging and non-conducting products of reduction. The cause of the loss of power in this case, I therefore think, is solely due to the exhaustion of the acid inside the porous mass as it combines with the protoxide formed; and the rise of power is due to the renewing of the strength of the acid by diffusion from the main body of the liquid.

If only a weak current is demanded from the cell, the diffusion may be rapid enough to keep the acid fairly strong, and no alteration of power need be noticed, but with a powerful current at intervals the alterations are more marked.

Mr. Bosanquet says that with some secondary cells made by him the alternations of power were so marked and so extremely rapid as to cause the carbons of his lamp to chatter. I venture to doubt whether anything like this rate of recuperation is possible, and I have known lamp carbons to chatter when supplied simply from a dynamo.

After the cell has been discharged slowly for a long time, with intervals for refreshment if necessary, it ultimately is quite exhausted. What has given out, the + plate, the — plate, or the acid? I think that in many cases the acid is the first to be consumed, and that further life might be given to the cell by changing the liquid, but of course this depends altogether on the roominess of the cells. The + plate may be usually the first to fail in a large cell, by reason mainly of the local action spoken of in the last article, which reduces, and, worse still, detaches, great portions of peroxide of lead. For this local action goes on uninterruptedly, though slowly, it must be remembered, whether the cell is producing a useful current, or whether it is standing idle; and a lapse of time is as deleterious to the + plate in one case as in the other. Still there are individual + plates which appear to resist this action much better than others, though for what reason it is hard to say. The — plate will probably last the

---

Digitized by Google

longest, though its active surface may ultimately get so crusted over as to be of comparatively little use.

I have spoken so far of the normal or theoretical discharge of the cell, but in practice it is no more easy to get the active layers to recede steadily from the front of the coatings to the back than it is to get them to advance steadily in the charging operation. On the whole, however, I think the irregularities during discharge are less marked than during charge, and that there is not the same likelihood for protuberances and excrescences of action to extend from the front to the back as from the back to the front, and this obviously because the one case is analogous to stable and the other to unstable equilibrium. In the ordinary use of an ordinary cell the plate is eaten away with fair uniformity unless it contains foreign metals; but in electro-depositing a metal any little excrescence gets magnified, and a rough and hillocky deposit is the easiest to produce.

The irregularity we have to look for during discharge, therefore, is simply isolation of portions of the coatings on a minute scale; so that, for instance, on the + plate particles of peroxide instead of being reduced may be reduced *round*, and being thus isolated from conducting communication with the + plate, must remain unchanged and useless. In this way grains of particles of peroxide remain mixed up with the reduced matter on the + plate to so great an extent that the reduction of the plate barely changes its colour. The litharge and sulphate formed do give the plate a lighter aspect, but so very large is the proportion of unaltered black peroxide mixed up with them that an unpractised eye could not tell by looking at it whether a layer of peroxide were "reduced" or not.

The same may be said to a less extent of the — plate, where a large proportion of metallic lead remains in isolated specks uniformly and abundantly distributed through the mass of sulphate and oxide, or whatever the rest of the lead has become changed into.

It must be understood that these detached particles, whether of lead or of peroxide, are of no use whatever, and that they simply act as a clogging obstruction to the current as well as to diffusion, for, though themselves conducting, they conduct to nowhere, and no current would think of making use of mere isolated specks of conducting matter lying in its path, but would go round and between them just as carefully as if they consisted of glass dust.

It is for this reason that nothing at all comparable to the quantity of electricity required to form a cell originally can ever subsequently be got out of it. This of itself is not of such pressing importance—except, indeed, where *weight* is a fatal objection; it would be sufficient in practice if all that was put into a cell when re-charging could be got out during the discharge. Unfortunately this also is not possible.

Still the difference between a charge quantity and a discharge quantity is not anything like so great as that between the original form quantity and a subsequent either charge or discharge; and if one were to discharge cells singly, and give them plenty of time, I see no reason why a very large percentage of the charge current should not come out of them. There would necessarily be *some* difference, by reason of the evolution of oxygen during charge, all this being irreversible action; but the amount of this may be kept pretty low. From a series of cells discharged together, however, there will often be a striking difference between the charge and the discharge, as already explained, simply because the cells may not be precisely alike.

Again, if the cells are discharged too rapidly, they can hardly be expected to give the same quantity as if discharged more nearly at the same rate at which they were charged. At the same time, I have not many numbers bearing on this point, and the inquiry is complicated by the periods that must be allowed for refreshment when strong currents are wanted.

The number of ampere hours a cell can give out, however, is not the really important matter. We must ask also at what electromotive force does it give them out? The cell should be discharged through an integrating ergometer to give a real measure of what it can do, not through a voltameter or galvanometer; and we should thus find a sad discrepancy between the work put into any cell with which I am acquainted and the work taken out. For the cell during charge is always at its best, and its electromotive force is high; but, during discharge the electromotive force gradually falls, until the last portions of current are leaked out of the cell with a miserable remnant of force which accomplishes nothing. It is as if we stored energy in a tall cistern, pumping the water in at the top and drawing it off at the bottom. If the cistern leaks there is an obvious loss of power; but, even supposing it perfectly water tight, so that the discharge quantity is equal to the charge quantity, nevertheless there will be a deplorable difference between the work required to pump it in, all at the top, and the work obtained at the bottom from the gradually failing head of water.

It is fortunately not quite as bad as this with a Faure cell. It is more as if the supply pipe entered the tank somewhere near the middle, while the exit pipe left at the bottom. Thus we should be pumping in the first half of the charge against about half the maximum electromotive force, and the second half against a gradually increasing force. The discharge electromotive force would be a continually decreasing one as before. This analogy, however, is rather too favourable; for it makes the initial electromotive force of the discharge equal to the final electromotive force of the charge—which is not the case. The closest analogy would be to suppose the supply pipe to be supported on a float at a height above the water equal to one-third the total height of the tank, and to rise with the level of the water, so that it is supplied at a pressure always one-third greater than that at which it is drawn off. To complete the analogy, the cistern must be supposed to leak slowly, so as to empty itself by long standing; and if it had an elastic and porous membrane stretched across it, some analogy to the failure of the cell to give a powerful current for long together, and to its recuperation when let alone, would be observed.

I have supposed the cistern to be of uniform diameter, but it may be hoped that Faure cells are cisterns with enlarged tops, or are conical vessels with the wide end upwards like drinking glasses. The more this can be exaggerated the better; and if the bottom of the cistern could be contracted to a pipe, and the top expanded into a large shallow tray, perfection would have been reached, especially if the height of the float were but small, and if the leaks were mended.

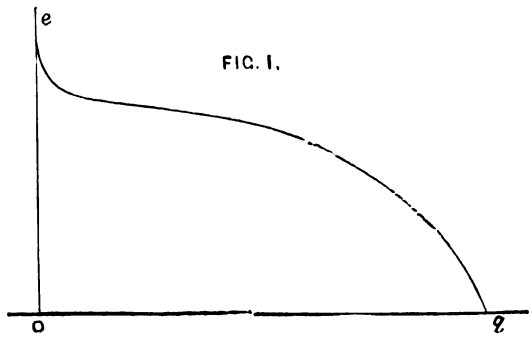

FIG. 1.

It will be understood that the reason I specify one-third of the cistern as the height at which the supply pipe is to float above the water is because the usual discharge electromotive force is 1·8 volt, and the usual charge electromotive is 2·4 volts. When you begin to charge the cell its electromotive force is less than this, and when the cells are full it is more; but 2½ volts is a good allowance per cell, the odd ·1 being sufficient to send the charging current through the resistance of the cell and connecting wires, at least when the acid has not been absorbed by long standing. And in discharge it is only at the first instant or two that you get a higher electromotive force than 1·8 volt.

By observations with an electrometer galvanometer and watch, the shape of the cistern corresponding to any given cell can be constructed; and the shape during charge can also be constructed, and its difference to that of the discharge appreciated without making use of the rough approximation of the float.

The outline of the cistern will be a curve having electromotive force—or e—as ordinates, and $\frac{dq}{de}$ as abscissæ, q being quantity of electricity given out by the cell as recorded by a voltameter, or as observed by means of a galvanometer and a watch. To understand how to draw the curve, first consider observations made with an electrometer and a voltameter, and let their indications be plotted, e for ordinates, q for abscissæ; then draw a curve with the same ordinates having as abscissæ the trig. tangent of the inclination of the tangents of the first curve to the vertical; this will be the outline required.

Fig. 1 shows the kind of appearance of the e, q curve; and Fig. 2 shows the curves e, $\frac{dq}{de}$. In the first the total quantity of electricity given out by the cell is represented by the length of the base line $O\,q$, while the area enclosed represents the energy of the discharge. In the second the area enclosed by the curve represents the quantity of electricity, and the work done by the discharge is represented by the moment of this area about $O\,X$. We may consider the curve of Fig. 2 as the outline of a cistern, or we may picture it to ourselves as a heavy horizontal plane pivoted on $O\,X$ as an axis, and consider the rotating moment which it has about $O\,X$. But, after all, Fig. 1 is the simpler curve, and it will show most instructively the relation between the work done in charging and the work obtained in discharging

Digitized by Google

the cell. Fig. 3 shows the charge and discharge curves superposed, the charge and discharge quantities being naturally drawn in opposite directions. O P is the charge curve, the quantity of electricity put into the cell being O N, and the work of charging being the area O P N; P B is the discharge curve, the quantity given out being B N, and the useful work the area B P N. The area O P B, of course, represents the loss of energy; the efficiency of the cell is the ratio $\frac{B P N}{O P N}$.

These curves for secondary batteries are as instructive as indicator diagrams for steam engines. They are, in fact, precisely analogous to them, and it would be not difficult to construct a machine for drawing them automatically, but it would necessarily be a long operation. The beauty of the steam engine indicator is that the charge and discharge of the cylinder take place too rapidly for the operation of taking a diagram to be by

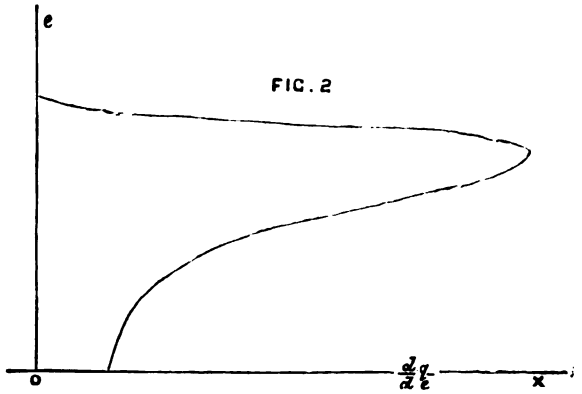

FIG. 2

any means a tedious one. The electrical indicator, however, need not in any way interfere with the practical work of the cell any more than the steam engine indicator does, and it would be most instructive to have them fitted up to cells made in various ways, so as to really learn all about their behaviour, and especially about the influence on efficiency of a lapse of time between charge and discharge.

When cells are being charged and discharged for experimental purposes only, care may be taken to keep the resistance of the circuit constant, for then the number of ampere hours *squared* does give a simple measure of the work of the cell.

I have not said much explicitly about one very important application of secondary batteries for which they seem better fitted in their present state than for actual storage by retention, viz., their use as regulators, in a branch circuit between the dynamos and lamps. The charge and discharge will then go on almost simultaneously, and the cells will, therefore, be in a high state

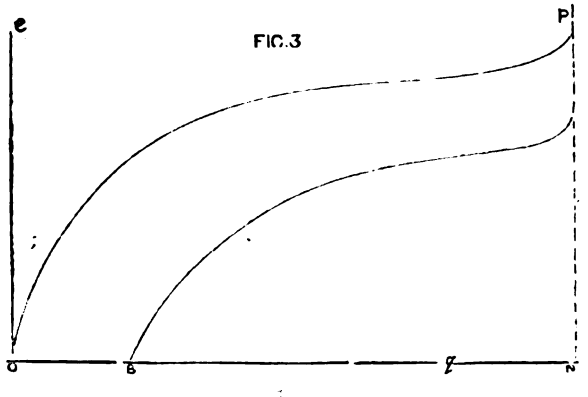

FIG. 3

of efficiency. The only danger is that the + plate may get peroxidised completely and crumble to pieces, a thing which may happen to any Faure cell if much overcharged.

For this regulating work a return to some form of the old Planté cell, with its low internal resistance, might be advisable, as great storage capacity would not be an essential unless, indeed, the cells had to insure one against an accidental breakdown of the engine or dynamo.

Again, some applications such as locomotion require light cells, and also sometimes a powerful current for a comparatively short time, such as a tramcar run. For such cases also something more like the old Planté might be useful; and in general cells for different purposes will have to be made on different plans, and an electro-store for a town will be a different thing from an electro-tank for a house, and this, again, from a little electro-box for a tricycle.

A question which naturally occurs to one on reading what I have said about the acid being sometimes the first substance to fail in the cell is—why it is not the practice to supply the cells with more acid and more space for it? The answer, I think, is, that the quantity of sulphate of lead in the coatings, and especially in the — coating, would be thereby increased, and that this sulphate of lead is very objectionable because it is so difficult to reduce. For, although Messrs. Gladstone and Tribe have shown that I was wrong in saying that sulphate of lead, by itself and as a paste, was quite incapable of reduction, yet the strength of current used by them, the time allowed, and the consequent waste of power in simply generating hydrogen gas renders it quite out of the question in practice to attempt to charge a cell whose negative plate is coated with nearly all sulphate of lead, and if an unlimited supply of fresh acid were accessible this is what the — coating would be likely, sooner or later, to become.

Another thing I want to say is that in Article No. 3, when speaking of the gas evolved from the cells while charging, I laid more stress on the hydrogen than on the oxygen. This was wrong. The gas evolved from charging cells is little else than oxygen and ozone; and if any hydrogen more than an occasional bubble or two is given off, it means either that the charging current is unnecessarily strong, or else that the cells are nearly full.

I have now concluded the present series of articles, and if it is noticed that I make no mention of the modification of Faure cells in which the coatings are supported in the interstices of cast lead gratings instead of being spread over the outer surface of plates, it is because I am dealing more with the scientific aspect of the subject than with the microscopic modifications which appear to constitute patentable improvements. What I have said about the active layer of operation during the formation of the cell remains, however, fairly true for these cast gratings, if for "back" we read portions next the lead, and for "front" portions near the centre of each hole; but that the layer of operations recedes in quite the same way during discharge I do not think likely, and it is not quite easy to see how the portion in the very middle of the holes gets acted upon during discharge. But if it does not it matters very little, as it would only remain inert ready for the next charging.

The doing away with the cloth material between the plates would seem to be an improvement, but I cannot think it safe. The risk of short circuiting, whether by dropping of substance out of the holes or by warping of the plates, is so great, and the damage done to a cell by short circuiting is so final, that some continuous insulation between the plates appears necessary, however troublesome and otherwise objectionable it may be.

Although the practical importance of secondary batteries is felt and recognised in a remarkable way at the present time——mainly, no doubt, by reason of the immense weight and enthusiasm of Sir William Thomson's opinion—and though a great deal of experience bearing on the subject from the practical point of view has now accordingly been attained, yet any one reading the "Recherches sur l'Electricité" of M. Gaston Planté, must be struck with the small advance we have made on his work, considered from the purely scientific aspect.

I had been unable to obtain a copy of this book till quite recently, and am struck on finding the whole details of the action of secondary cells worked out with such completeness and precision. He knows that the loss of power of a cell is caused by a scum on the — plate, a fact which I thought I had observed. He speaks about local action on the + plate as clearly as Messrs. Gladstone and Tribe, and he suggests that the scum on the — plate may in some cases be an extremely thin coat of peroxide—a fact which the researches of these chemists seems now to have established. Whatever future may lie before lead secondary batteries as stores of power on the large scale, the name most imperishably associated with their early development will be that of Gaston Planté.

ROYAL SOCIETY OF EDINBURGH.—At the third ordinary meeting of this society, held this week, Professor Crum Brown communicated the results of a large number of experiments made by Mr. Thomas Andrews, Assoc. M. Inst. C.E., "On the relative electro-chemical positions of wrought-iron, steels, cast metal, &c., in sea water and other solutions." Mr. Andrews found that the relative electro-chemical positions of these metals were not static, and a marked result of the observations was the steadily changing deflections noticed from the commencement, frequently resulting in a complete exchange of the electro-chemical positions of the metals. The practical deduction was that the danger from greatly increased corrosion in sea water, which the observations displayed, was not to be disregarded by the engineer in dealing with these metals.

1882.

We had no intention of taking up part of three issues with our annual summary when we first commenced to write, but so it happens. Loose threads must be taken up, and information incorporated which had not reached us soon enough to take its proper place. We have, then, to return to the progress of electric light in 1882. The work of the

PILSEN, JOEL AND GENERAL ELECTRIC LIGHT COMPANY has been mostly preparatory. The company was registered on May 15, the share capital during that period of excitement being subscribed seven times over in three days, and the allotments made on May 23. Suitable works have been obtained at the Malden Factories, Kentish Town, and fitted up for producing the electrical apparatus manufactured by the company. Besides this preparatory work, the company has carried out installations at Messrs. Baker and Co.'s (Holborn); Messrs. Crisp and Co.'s (Seven Sisters-road); Messrs. Hopkins and Pegg's (Shoreditch); Messrs. Dewhurst's (Manchester), Messrs. Lewis and Co.'s (Liverpool). At the latter establishment 57 Pilsen arc lamps are used. Several of these lamps are also in use by the Royal Engineer Committee, Brompton Barracks, Chatham. Quite lately a contract has been signed to light the premises of the Union Society at Oxford. This will be one of the most important installations of 1883, and if the company carries it out to the satisfaction of the Oxonians there is no doubt it will lead to a large amount of work in the country mansions throughout the kingdom. From a business point of view, success here means an advertisement that could hardly be surpassed for effect anyhow or anywhere.

The NORTHERN ELECTRIC LIGHT COMPANY was the first Scotch electric light company registered, being formed in October, 1881, by a few leading local gentlemen in Dundee. It is purely a supply company, and does not manufacture. It supplies the apparatus of any manufacturer as desired, but has hitherto generally used Siemens's machines and arc lamps and Swan incandescent lamps. The work carried out has been of various kinds—arc lighting for shipbuilding yards, for dye works, for jute factories, and for paper mills; incandescent lighting for private mansions, hotels, public halls, newspaper offices, &c.; while, besides these permanent installations, a large number of temporary installations have been made for exhibitions, flower shows, bazaars, banquets, *conversaziones*, &c.

The ELECTRIC LIGHTING SUPPLY COMPANY have been principally engaged in the production of electrical fittings during the past year. Some idea of the very extended demand that has arisen for this kind of work may be gathered from the fact that they have sold upwards of 3,000 of Hedge's patent switches, besides a large number of the ordinary kind. The company's works are at York-street, Westminster, where they are also manufacturing a dynamo known as the Franklin-Bürgin, the essential parts of which are as in the ordinary Bürgin. One of these machines is working incandescent lights throughout the Victoria Mansions, and a second is to light the new restaurant. The company have a large order in process of execution for the Liverpool docks, the system of lighting which is simply an extension of the original plan of powerful arc lights suspended from the top of lattice iron poles so as to illuminate for 180 yards on every side. In order to meet the demand for carbons and battery plates, a manufactory has been started on a very large scale by the Barnsley Carbon Company at Barnsley. The carbons are made on the American plan of pressing a number at a time, and from a refuse material which resembles very closely the carbon from petroleum, to which the American carbons owe their purity. The present capacity of the works is equal to 10,000 carbons a day, the process of making taking about three weeks.

THE SWAN UNITED COMPANY.—The following is a further account of some of the work merely indicated in our previous paragraph on this company:—Ss. "Manapouri" and ss. "Wairarapa," belonging to the Union Steamship Company of New Zealand, built by Messrs. Denny Brothers, Dumbarton, were each lighted throughout with 145 Swan lamps and two differential arc lamps for temporary use while discharging cargo. The current is supplied by Siemens coupled alternate current generators, which are driven direct. The lamps were adapted to the plated and bronzed oil lamp fixtures supplied by the shipbuilders. The whole of Messrs. Coxon and Co.'s Newcastle-on-Tyne drapery establishment has been lighted. The installation consists of 46 50-candle

Digitized by Google

lamps and 76 20-candle lamps. The lamps are suspended from plain drop pendants with ornamental bell-shaped obscured globes. The 50-candle lamps are used in the windows. There are two novelties in connection with this installation, *i.e.*, the outside reflecting lanterns, in each of which two 50-candle lamps are placed, and the illumination of air tight glass cases with obscured Swan lamps fixed inside them. The current is supplied from a Siemens alternating current machine, which is driven by a Tangye horizontal engine. Messrs. Coxon and Co. also have a Siemens direct current machine driving a 3,000-candle arc lamp at the corner of their premises, suspended outside so as not to interfere with the Swan lamps inside. The new house of T. Richardson, Esq., M.P., Kirklevington, has been fitted up with leading wires necessary for installing about 90 lamps, and the order has been received for the supply of steam engine and dynamos for completing the installation. The machines to be used are two of Siemens's S D 7 machines, which will be driven by a Robey vertical engine and boiler.

The ss. "Goorkha," of the British India Steam Navigation Company, was fitted up whilst building at Messrs. Denny's yard with 91 Swan lamps, and four arc lamps for temporary use on deck. The current is supplied from a Siemens alternate-current generator, driven direct. The lamps are fitted in the Swan Company's silver-plated globe pendants in the saloon, and on plain-plated brackets in the state rooms, and bronzed brackets in the engine rooms. The ss. "Cephalonia" and "Pavonia," Cunard Steamship Company, were each fitted throughout with 320 Swan lamps and two arc lamps for temporary deck use. The Swan lamps were fitted in the saloons into the plated oil pendants, and in the state rooms into the three-cornered oil lanterns. In other parts of the ships plain brackets and obscured globes were used, and in the engine rooms some of the lamps were made portable. The current is supplied by two Siemens alternate current machines.

The installation at Blaydon Hall, the seat of Sir M. W. Ridley, Bart., consists not only of Swan lamps, but also of motors for conveying the power of the home farm engine to other portions of the estate. Eighty lamps are installed in the house, and 15 in adjoining buildings. The house is distant 600 yards from the home farm, and the current is conveyed in underground insulated leading wires. There are two motors fixed, the one for driving a water pump, which sends water either to the house or to the home farm for use in the boiler, and another is fixed at about 300 yards distant, in a wood yard, where it drives a circular saw and an ordinary mortar mill. The dynamos and motors used are Messrs. Siemens's direct current machines, driven by the farm engine. Messrs. Rowntree, Son, and Co., Scarborough, last year completed the building of a new drapery shop, and gave orders to the Swan Company to light the building with 220 Swan lamps. Most of the lamps are supported in groups, under ornamental silvered glass reflectors, with silver-plated mountings. Other lamps are suspended by scroll brackets attached to the counter rails. The current is supplied from a Siemens alternate current generator, driven by a 16 horse-power Otto gas engine. The jerking motion of the gas engine is completely got over by the addition of a fly-wheel on the exciting dynamo, and by the use of long slack straps. An interesting feature in the installation of Morland House, the seat of Captain F. Markham, is the use of a turbine. This installation consists of 40 Swan lamps fitted throughout the house. The current is supplied from a Bürgin dynamo machine, driven by a vortex turbine supplied by Messrs. Gilkes and Co., of Kendal. Messrs. J. H. Gartside and Co., Buckton Vale Dye Works, Stalybridge: This installation will consist of about 630 Swan lamps when all are fitted up. The whole establishment will be fitted with Swan lamps, to the entire exclusion of gas. About 210 lamps are now working satisfactorily. Some portable lamps in wire guards have been supplied to enable the workmen in charge of the calico printing machines to examine minutely the fabric as it passes across the rollers. The current is supplied by three of Siemens's alternate current generators, driven by means of belting from the mill shafting. The installation at Messrs. W. F. Moore and Son's, Tromode, Isle of Man, when complete will consist of about 220 Swan lamps, and about one-half the total number of lamps installed will be fixed in the mill, and the other half between the proprietor's and manager's private residences. They will be supplied with current from two of Siemens's alternate current generators, driven by belts from the countershaft of a water wheel. All the wires, &c., are laid, but some delay has occurred in the preparation of the driving arrangements. The paddle-steamer "Lonsdale," belonging to Captain Deane, was built by Messrs. R. Steele and Co., of Greenock, under the superintendence of Mr. J. F. Spencer. She was lighted by the Swan Company with 44 Swan lamps supported on ornamental plated pendants and brackets, also supplied by the Swan Company. The current is supplied from a Siemens $S D^2$ machine, driven by a belt from a Tangye vertical engine. The dynamo is placed on a sliding bed, to enable the belt to be tightened when the machine is running. At Messrs. Webb Brothers, Randalstown, Co. Antrim, 30 Swan lamps, in various portions of this firm's linen weaving factory, are used. The power is obtained from a turbine wheel, and the dynamo machine used is Siemens's S D 7. An installation of 80 Swan lamps in the drapery establishment of Messrs. Duff and Rowntree, Bishop Auckland, has been made. The lamps are fixed in the work rooms as well as in the ware rooms. On market days and other special occasions a Weston arc lamp is used outside the premises. The current is at present supplied by a Siemens alternate current machine driven by a coupled Tangye vertical engine, but Messrs. Duff and Rowntree intend to replace this machine with a Ferranti or other machine. The ss. "Hammonia" is being fitted up for Messrs. J. and G. Thomson, of Glasgow, the builders, and is to be lighted throughout with about 100 Swan lamps. The current will be supplied from a Siemens coupled alternating-current machine, driven by means of a single belt from the fly-wheel of a Tangye vertical engine. The machine is fixed on a sliding bed, so that the belt can be tightened when the machine is running. Orders have been received for fitting up the ss. "Nerbudda," British India Steam Navigation Company, now building at Messrs. Denny's yard, with 90 Swan lamps, in a similar manner to the ss. "Goorkha." The driving power will be a similar arrangement to that adopted on the ss. "Hammonia," viz., a Tangye vertical engine, driving coupled alternating machine.

THE JABLOCHKOFF COMPANY.—During the year this light has been used at Ulverston, at the mines of Messrs. Harrison, Ainslie, and Co., giving complete satisfaction, and there is a great probability of the use of the light being extended. The Jablochkoff light has also been installed at the Cobalt mines of Sir Hussey Vivian, in Norway, and at the Newhaven Harbour extension works of the Brighton Railway Company. A large amount of work is anticipated. Some is in hand, such as that at the Gaiety Restaurant, where Messrs. Spiers and Pond will use about 30 Jablochkoff and 50 Swan lamps to light table d'hote, grill room, bar, &c. The current will be supplied from the Jablochkoff Company's new works in the Belvedere-road. We understand that the well-known Magazines du Printemps, Paris, rebuilt after a fire believed to have originated with the gas, will be lighted with 350 Jablochkoff lights, of which 150 are already fitted. We must not forget the indoor installation of Messrs. Womersley and Co., in the Poplar-road, who have the necessary apparatus for 20 lights.

We trust that the current year will be favourable to electric light work, and for the various companies embarking in this new field of enterprise.

THE INDIA RUBBER, GUTTA PERCHA, AND TELEGRAPH WORKS (SILVERTOWN).—These works, which we generally call the Silvertown Works, have been very busy during the year manufacturing and laying the West Coast of America

Digitized by Google

cables. The manufacture of cable forms but a branch of the company's works, other branches being devoted to the manufacture of all kinds of telegraphic and electric apparatus. The company, we believe, manufacture Bright's fire alarms, a large quantity of telephonic apparatus, batteries of various kinds, a good deal of torpedo, cable, and firing apparatus, besides india rubber goods, &c. Altogether it is one of the finest establishments in the world, and is admirably conducted, every effort being taken to ensure the goods being manufactured in the best manner. To return, however, to the cable work, we cannot give the exact lengths of the various parts of the cables mentioned, but the total length is approaching 4,000 miles. This company manufactured the Saghatien-Tartary cable, 63 miles, for the Great Northern Company; the Aberdour-Granton cable for the Post Office, and for the West Coast of America Company, the Chorillos-Payta cable, 553 miles; the Payta-St. Elena, 222 miles, the Galveston-Brownsville, the St. Elena-Buenaventura; the Buenaventura-Pearl Island; the Salina Cruz-Libertad; the Libertad S-Juan del Sur; the S. Juan del Sur-Pearl Island and the Pearl Island-Panama cables. They also manufactured, for the French Government, the Bona-Bizerta cable, as well as the Sourah-Sfax, Sfax-Gabes cables. It will be seen that altogether this has, as we say, been a busy year, and when we remark that all the land line connections, the instruments, &c., for the West Coast of America cables, were manufactured at Silvertown, it will give some idea of the work. We have from time to time recorded the success in laying these cables, so that we may leave the above list to speak for itself, trusting that the record next year may be as good.

Latimer Clark, Muirhead and Co.—During the past year this well-known firm has been very busy manufacturing electric light apparatus of various kinds, and for the purposes of this work have purchased the Northumberland Works, Millwall, the old works in Regency-street, Westminster, being too small, although they have at various times been greatly enlarged. The heaviest part of the manufacture is now carried on in the new works, the lighter parts only being continued at Westminster. The past year has, we believe, been, on the whole, the busiest that the firm have experienced. Large numbers have been supplied for various parts of the world of Muirhead's patent compound iron telegraph poles, and the increased demand for these poles shows they are appreciated over other patterns. In the more delicate and scientific work which largely occupies this firm, we notice that they have made the duplex apparatus for the Paris New York Telegraph Company's cable, between France and America, and also for one of Mr. Jay Gould's Atlantic cables. Dr. Muirhead has but just completed the installation of the duplex system of working on the latter cable from Cornwall to Nova Scotia, and it works with perfect success. This duplex system is now in daily operation on upwards of 20,000 miles of submarine cable, all of the longest laid, and therefore the most difficult on which to adjust the system. It is needless to explain to most of our readers that duplexing does not mean doubling the cable, but arranging certain apparatus so that the cable can carry in a given time double the number of signals that could be carried under ordinary circumstances. Double is used with a general and not with an exact signification.

Telephones.—In order to complete our review of telephonic work for 1882 we have still to refer to Sheffield and Dundee. The Sheffield Telephone Exchange, which is owned by Messrs. Tasker, Sons, and Co., establishes itself more firmly as an auxiliary to business year by year. That it gives good service is evidenced by the fact that the number of subscribers steadily increases, and that the calls have now reached an average of 1,400 per day. The whole of the "switching" is done by three operators in the central office, on an exceedingly simple plan. Owing to the efficiency of the general maintenance, not more than three faults occur weekly. This efficiency is exceptional, and the management attribute much of it to the use of the Johnson transmitter and Bell receiver, and to the very substantial way in which the lines have been constructed. The extraordinarily severe storms of the past and present winters have not in the slightest degree weakened the stability of the overhead system, not even to the breaking of a single wire. Messrs. Tasker, Sons, and Co. are now devoting much of their attention to electric lighting; they have lately carried out some very successful installations, and others are now in their hands which have not yet been completed. The Dundee and District Telephone Company is another very successful locally established concern. It was started in 1880 under the management of Mr. G. Lowdon. The subscribers now number 277, and as an indication of the use they make of the exchange we may mention that the calls for the week ended Saturday last (January 13) amounted to 12,540.

CORRESPONDENCE.

THE ACTION OF MICROPHONES.

TO THE EDITOR OF THE ELECTRICIAN.

Sir: What I wished to call Mr. Smillie's attention to, and what he seems not to have noticed is this—that if the carbon varies its resistance under minute changes of pressure as he says, there would be no necessity for the platinum stud, but a piece of carbon to which two binding screws were attached would answer equally well. Let Mr. Smillie examine a Crossley transmitter. It may assist him in altering his opinions. That vibrations take place in the transmitter between the contacts is certain, and if they are too rapid for our ears to distinguish, that is the fault of the ears. The reason carbon alters its resistance more than brass is owing to the difference in form, not of material. If Mr. Smillie were to glaze the surface of a piece of carbon until it were as fine as the brass button entrusted to your charge, Mr. Editor, and afterwards make the surface of the brass button the same exactly as the carbon had been, we should find the greatest variation of resistance to take place in the brass instead of the carbon. Some very fine brass filings, with a little dust thrown in, would show a more variable resistance than the brass button.—Yours, &c., J. Rathbone.

5, Prospect-place, Treorchy, S. Wales.

TO THE EDITOR OF THE ELECTRICIAN.

Sir: I have been somewhat amused by the very original researches made by Mr. Smillie, and, but for his second letter on the subject, I would not have ventured into the discussion. I think that, having for some years devoted my attention to the subject, I may, perhaps, be able to help clear away the mist with which he is so obviously enshrouded. Taking the latter part of the third paragraph of his second letter—"The resistance of the circuit being diminished, a corresponding diminution of current takes place when the pressure is removed." This appears to my poor apprehension of Ohm's law, and, in accordance with my experience, to point to the conclusion that electricity in Glasgow differs very considerably in its laws and actions to electricity elsewhere, and, therefore, it would probably be unjust to decide that the conclusions of Mr. Smillie are erroneous. Mr. Smillie appears to conclude that because the platinum follows the carbon for a quarter of an inch when the carbon is lifted by hand, it will also follow it with the same facility when the carbon is driven away by impact on the diaphragm. The laws of physics should prove the contrary. Substitute for the diaphragm, platinum, and carbon, three elastic substances suspended each in contact by a string or other means which will allow them each to vibrate freely. Give either of the outer substances a smart blow, and see what happens. If the three bodies are freely suspended there will result a separation between them, the equivalent of the carbon, the diaphragm equivalent being struck, will fly away. If, instead of being freely suspended, the bodies are suspended by springs, the result will only be modified in degree, and in case actual separation does not take place, as it inevitably will do if the blow is hard enough, a diminution of pressure will result between the platinum

Digitized by Google

and carbon equivalents. This corresponds to a diminution of current strength, because the resistance is in some inverse proportion to the pressure between the electrodes. I should have deemed it impossible that any one should require a demonstration of the fact that the resistance introduced into a circuit by the contact of carbon and carbon or other conductor varies inversely with the pressure. It is altogether too late to discuss this now, but why carbon should behave in this manner, and why a brass button will not, might prove a more valuable subject. I may say, in conclusion, that carbon is by no means singular in this respect, and that good transmitters are made without it.—Yours, &c., W. E. H.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I have carefully read the pros and cons put forth by each party to this discussion, and without taking my stand upon either side, I will just state the experiments I have myself tried, and leave your readers to draw their own conclusions. A few months ago, thinking it possible to bring out a relay transmitter, I obtained a circular box, the lid of which was made to screw on so as to clamp a diaphragm. Through the centre of the diaphragm I inserted a piece of German silver wire pointed (about 16 B.W.G.), and fixed tight to the diaphragm by small adjusting nuts on either side. To the bottom of the inside of the box I fixed a block of carbon with a hole in it containing carbon powder, secured from falling out by a piece of wood on top and a thin piece of ebonite on top of it, again sealed firmly to the top of the carbon with Chatterton's compound. When the diaphragm was placed upon the box and the lid screwed firmly down, the wire pressed well down into the powdered carbon, so that when speaking in the usual way towards the hole in the lid the sound waves impinged against the diaphragm, causing it to vibrate, and thereby moving the wire up and down in the carbon dust, and the words were reproduced at the receiving end, as though they were spoken through a small-toothed comb, in a loose and shaky or grating kind of manner. I tried the experiment with the powdered carbon, pressed well in so as to make it solid, with fine and with coarse powder, but with not much better results. I then enlarged the hole in the block, and fixed a plug of carbon to the diaphragm, so that when the diaphragm was fixed down the plug lightly touched the powder. I got much better results from this, but the loose grating sound was not altogether got rid of, so I tried another diaphragm on top of the first one, but kept apart from it by an india rubber ring. Upon the centre of the top diaphragm I fixed a small stud that just projected very lightly against the lower one when motionless. From this arrangement I obtained better results than I have ever yet heard produced by any other transmitter. The voice was full and loud, the articulation beautifully clear and distinct, and when the speaker shouted into the transmitter the voice came out of the receiver and sounded through the room sufficiently loud to have been heard 10 or 12 yards away. The faintest whisper could be heard quite distinctly.—Yours, &c., GORDIUS.

London, Jan. 15.

STATIC ELECTRICITY IN QUANTITIES.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I am afraid I cannot work this matter out to satisfy Mr. Von Tunzelmann, p. 207, because it will branch off in so many different lines. I must refer him to my complete work when it appears.

Words generally have several meanings, and it is not easy to convey ideas from one mind to another without some misapprehension from this cause. The distinction between quantity and degree is very clear, yet I do not care to put it into a definition. We have degrees in temperature, we cannot have quantity. So with force as pressure, that is to say static force has no quantity, but has degree; and what I mean is that, when we define a unit quantity of a force, we are not expressing static force itself, but the work it can do upon a quantity of something else. That is the same idea which I state as to electricity itself, viz., that the so-called unit of electricity is simply a measure of work done upon matter by electric force.

The same idea appears to be embodied in the quotation from Newton, which is misinterpreted in that from Professor Clifford, the latter embodying what I consider is the erroneous conception of the unit of electricity. How can force *be* "the change of momentum?" This is really what the unit measures, but the *force* is not the *change*, but the *cause of the change*. Just so the force of gravitation or of steam in a boiler can be measured as degrees of pressure, so many pounds per square inch; but this is not a quantity. To give it a quantitative value, it must be rendered dynamic, and expressed really as the energy due to its unit actions; for unit force and unit energy are the same, because 1 and 1^2 are the same length, and by the law of conservation cause and effect must be equal, and most of our forces (steam pressure, for instance) are merely mathematical expressions for the energy which is expended in their production, which is of course equal to the energy developed by them.

Faraday's ice pail experiment is so thoroughly misunderstood, and its real meaning so utterly obscured by the mathematical theory of electricity, that I cannot pretend to touch upon it here. If Maxwell had lived he would have treated it very differently in due time. His posthumous work shows him gradually passing from the artificial doctrines of electricity, and adopting the same as those I endeavour to sustain; and what is more, most of the leading electricians are unconsciously adopting the same course. All recent books show the temporary confusion of thought due to the change of theory which is occurring.

I told Mr. Von Tunzelmann that I do not hold electricity to *be* energy, and I must now tell him that I do not "consider electricity to be the square root of energy." Electricity is to me nothing but a word; unfortunately, it is a word used to embody two distinct sets of phenomena, and, as I am obliged to use it, I must needs be open to this appearance of confusion when a reader chooses to limit the meaning to one of those it covers, because I cannot explain this every time I write about electricity. All electricians have been involved in this same confusion and difficulty owing to electric quantity and electric energy being both called "electricity," while they hold the relations to each other of numerical order and its square. I do not care to go into the questions of dimensions, and deductions to be drawn from them. But I consider that there is an aspect in which the units of electromotive force, of current, and of resistance are one and the same values, and that aspect is the energy represented in them.

Consider an illustration employed by Dr. Siemens in his B.A. address, and derived from Sir W. Thomson. I quote from Vol. IX., p. 344.:—"Imagine a ball of conducting matter so constituted that it can at pleasure be caused to shrink. Now let it be electrified and left insulated with any quantity of electricity on it. After that let it be connected to the earth by a not perfectly dry silk fibre, and let it shrink just so rapidly as to keep its potential constant. The velocity with which its surface approaches its centre is the electrostatic measure of the conducting power of the fibre. Thus we see how 'conducting power" is in electrostatic theory properly measured by a velocity."

Be it so, but current is necessarily a velocity, and taking the proper unit Q it would be this same velocity. But would not this velocity and unit be also the measure of the "potential?"—Yours, &c., J. T. SPRAGUE.

CABLE TESTING.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: With reference to the articles on submarine cable testing now appearing in your journal, I take the liberty of directing your attention to my paper, "Faults in Submarine Cables," in Vol 3, pp. 372-82, of the *Journal* of the Society of Telegraph Engineers. Mr. Clark, in his remarks thereon

Digitized by Google

(*vide* discussion), characterised my plan as better than Lawes's and Lumsden's, and more scientific than any yet proposed, &c.

If the writer of the articles would make use of my paper at the proper time I would be obliged.—Yours, &c.,

J. J. Fahie.

13, Craven-street, W.C., 15th January, 1883.

"GLOW" LAMPS.

TO THE EDITOR OF THE ELECTRICIAN.

Sir: In reference to the discussion going on as regards the nomenclature of lamps, if we are to judge from their appearance, I think the simplest way to settle a discussion will be to apply the term "glow" to such lamps as the Edison, especially those as seen on the Holborn-viaduct, retaining the word "incandescent" for such lamps as the Lane-Fox, Swan, and Maxim, which are worked at a higher temperature, and show a white appearance.—Yours, &c.,

Rue Colbert, Paris, Jan. 15, 1883. Blank.

POSTAL TELEGRAPH SERVICE.

TO THE EDITOR OF THE ELECTRICIAN.

Sir: The revision of the commercial staff of the Postal Telegraphs has elicited considerable public interest, and to a lesser extent the pecuniary readjustments lately promulgated in the engineering branch have received outside attention and support; but nothing has yet been done or said with regard to that numerous body of public servants who constitute the working staff of the last-named branch. This might be attributed to a want of influence amongst themselves, or, perhaps, the reason might be found in their being less ready to "air" their grievances through the friendly channel of the Press; hence the fact that no attention has as yet been attracted to their condition.

If you will allow me space I shall endeavour, as briefly as possible, to state a few of the more important grievances peculiar to this section of Government servants.

To commence with, they may be conveniently classified under two heads:—First, Mechanics; second, Linemen.

A comparison between the former and telegraph clerks is somewhat curious. Under the telegraph companies the rate of remuneration for mechanics was similar to that paid at the present time. The maximum rate in the provinces has remained throughout all departmental changes almost unaltered, whilst his fellow worker, the telegraphist, has had his maximum increased two-fold. But the majority of mechanics have other reasons for considering themselves unfairly dealt with by the department. Those who have entered the service since the transfer of the telegraphs are debarred from participating in many of the privileges generously granted to State servants. In cases of sickness his pay is stopped, annual holidays are not allowed except at his own expense, and when incapacitated, possibly after a life's service, he receives no superannuation allowance. The official reasons assigned for this state of affairs are, that mechanics are paid the market price, and that they have at all times a market available for their labour. This dictum practically means that were his services dispensed with in the provinces he must necessarily direct his attention to London. It has been the experience of many provincial mechanics who have left the service with the natural desire to improve their prospects that the telegraph department is the only market for their talents in this country. But the question arises, is the department confined to *employés* destitute of another market? Evidently not, when the best telegraphists are being continually attracted from the service by cable companies and others.

With regard to that portion of the staff which comes under the second head, a similar injustice exists, except in the case of linemen detailed to maintain a sub-district, when they receive the usual Civil Service appointment. But they do not comprise all the linemen constituting a provincial engineer's staff. At important stations, for instance, men are kept continuously employed maintaining batteries at a lower rate of pay than ordinary linemen. This work is none of the healthiest; the battery compartments, as a rule, in large offices, are situated in cellars where light and pure air are not to be expected, and, although battery-men are just as essential to the working of a district as linemen, they are, like mechanics, kept outside the pale of an appointment. It would seem as though the intention were to deprive those who have the most confined and unhealthy occupation of relaxation from duty and help during sickness.

The above are the more glaring anomalies existing within the branch itself, which are certainly sufficient to call for redress. But it will be seen that the whole staff requires attention from the Postmaster-General similar to that bestowed upon other branches of the Post Office telegraphs. Both mechanics and linemen have every reason to feel dissatisfied with the system of promotion pursued at the present time. Vacancies occurring, such as inspectorships, in the engineering branch are, without an exception, filled up from the commercial staff. Again, within the last few years the department has undertaken to manufacture its apparatus, having purchased a factory in London for that purpose. This would necessarily create a number of new appointments; still, we have not a single instance of any of these posts being offered to a provincial mechanic.

Mechanics and linemen when they reach their maximum rate of pay have the remainder of their lives before them destitute of any hope of further promotion. These anomalies in a branch of the civil service which prides itself on its impartial and unfettered system of promotion certainly look like matters requiring parliamentary ventilation. Much has been said with reference to the continued indifference of the department to the acquisition of technical knowledge by telegraph clerks, but what can be hoped for by the amateur technical worker when the professional receives such scant encouragement?—Yours, &c., Provincial.

SELF-REGULATING DYNAMO MACHINES.

[We had intended that with our comment on this correspondence in our issue of January 6 the correspondence should cease, and it is only because there still seems to be some misunderstanding in the matter that we again allude to the subject. In our summary of the work of 1882 we credited Messrs. Crompton and Co. with being the sole makers of the "compound machines." The term self-regulating is preferable to that of compound. The following is taken from a circular issued in New York, dated January 2, 1882:—

Dr. Higgs's System of Regulating Dynamo-electric Machines.

One of the most important and valuable inventions of Dr. Paget Higgs is his method of rendering the regulation of dynamo electric machines automatic.

This system consists in placing proper proportions of the coils of the field of force magnets in both the main and shunt circuits, by which means all auxiliary mechanism is avoided and the machine delivers to the working circuit at all times precisely the amount of current required.

This is the only system by which a dynamo machine, without auxiliary mechanism, is made capable of reducing or increasing the power absorbed according to the amount of current required, the power producing the current being "saved" in proportion as the current is lessened.

This system is now in operation. Its practical working is shown by switching the same current from a 4,000 candle-power lamp to a small incandescent lamp without any change whatever in the current or machine, except that which this system automatically produces and without any injurious effects upon the small lamp, the galvanometer placed in the circuit showing the instantaneous reduction of the current and potential corresponding to the reduction in the work done.

It is plain that no method of regulating that simply turns aside the portion of current not required—as surplus water is run to waste—can be economical like a method that lessens the current itself when the whole is not needed, and thus saves the power required to produce it; and it is equally evident that any mechanical method of controlling a current that does not diminish its production cannot be safe, for in case of any accident to the mechanism, the full current is at hand to do its mischief with

Digitized by Google

undiminished power; whereas, the improved arrangement devised by Dr. Higgs—in case of any accident throwing the current out of its legitimate use—instantly reduces it to harmless proportions. This, in view of the accidents liable to occur from powerful electric currents not thus regulated, is a point of great moment.

It is worthy of remark, also, that Dr. Higgs's system is applicable not to one form of dynamo machines only, but to nearly all kinds and varieties made; and while he has designed a particular style of machine—in which, by utilising the electric and magnetic forces in a thoroughly scientific manner, he produces given results with far greater economy than they are otherwise effected—his system of safe and economic control is by no means limited to his own machines, but in a greater or less degree is applicable to all.

This system may be used in regulating currents for the electric transmission of power as well as for the production of electric light, and, in some respects, to even greater advantage, for it makes it practicable to use a greater number of small motors in the same circuit than could be used by any other process, and it secures the machinery perfectly against any danger from "racing" as the work varies or any part of it is stopped.

The great utility of such a system of regulation in the numerous forms in which the electric current is now employed in electric lighting and as a motive power must be apparent to all, and it is with much satisfaction that attention is called to an improvement of so great value at a time when the introduction and use of electricity in the arts is engaging to a large extent the interest of the whole civilised world. Patents on this system have been secured in nearly all the leading commercial countries, and the fact that they have been granted without technical reference is very gratifying evidence of the unquestionable originality of the invention.

Other Inventions. — In the pursuit of his labours as a scientist and electrical engineer, Dr. Higgs has devised various other improvements, some of which are inventions of special value. Among these are his storage battery, proved to be of remarkable utility; his incandescent lamp, burning brightly and steadily without a vacuum, particularly adapted to the lighting of state rooms on shipboard as well as offices and dwellings; his plate lamp for mast-head and street and factory lighting, and burning nearly as many days as ordinary arc lamps burn hours without change of carbons, and his carbon rod lamp, entirely enclosed in a sort of automatically produced vacuum, whereby the carbons are indefinitely preserved, both the last named being without outside conductors or clockwork and automatically regulated at the machine.

These and other important improvements, completed, or in process, are mentioned as indicating the directions in which Dr. Higgs's work as a scientist and inventor is extending, and as desirable accessions to his very remarkable achievement of completely regulating and controlling the dynamo electric machine and current.

The following is from a *private* circular of the Electric Carbon, Storage, &c., Company, of Leith, dated October, 1882:—

The company's machines, as worked under the patents of a well-known electrician, are self-regulating, so that when any of the lamps are put out, the power used is automatically reduced. This is the only system by which a dynamo machine, without auxiliary mechanism, is made capable of reducing or increasing the power used according to the amount of current required. It is plain that no method of regulating that simply turns aside the portion of current not required—as surplus water is run to waste—can be economical like a method that lessens the current itself when the whole is not needed, and thus saves the power required to produce it. Even where the power saved is not important, this self-regulating principle effects great economy in the amount and character of attendance required.

Mr. Jackson, the manager of the company, writes:—"For the last three months we have been selling our compound dynamo machines."

Dr. Higgs thinks that we are doing him a wrong in attributing manufacture to Messrs. Crompton solely, admitting the wrong, if any, to be inadvertently done. Now, Dr. Higgs certainly sees our difficulty, viz., of ignorance. The American circular never had publicity in England, and the Scotch Company's circular is marked private.

Dr. Higgs gives us the fifteenth claim of his English patent:—"I claim the division of the exciting coils of magneto-electric machines by placing the coils of part of the magnets in a shunt circuit, and the remainder in the main circuit, either in the receiving or transmitting machines, &c."

So far as we are concerned, the publication of these extracts enables our readers to judge of the facts of the case for themselves. We have no feeling in the matter except to arrive at the truth. We have, however, one very strong opinion, and it is that, if these "cute" Yankees and Scotchmen object to publicity, they have no one to thank but themselves if they find half a dozen other claimants for a particular design. The world will not stand still to please them, and, speaking for ourselves, we shall always describe the machine and credit the makers of a new machine brought before our notice. There is such a thing as independent investigation and discovery, and A. B. must share the honour with C. D., although A. B. discovers six weeks, months, years, &c., before C. D., yet keeps his discovery secret till after C. D. has made it public to the world. We do not think the publication of Scrutator's letter would be useful. We agree with him as to the expediency of keeping the facts he states well in mind.—Ed. *E.*

THE ELPHINSTONE-VINCENT MACHINE.

As long ago as November 29, 1879 (*The Electrician*, Vol. IV. p. 21), we gave an account of this machine in the form of an abstract of a paper read before the Royal Society. In the same volume, p. 225, will be found a description of further experimental results obtained by Lord Elphinstone and Mr. C. W. Vincent. The machine upon which these gentlemen have been so long at work is now being manufactured by Messrs. Paterson and Cooper for use. We recall the peculiarities of the machine, which will easily be understood from the accompanying figures, showing (Fig. 1) a cross section

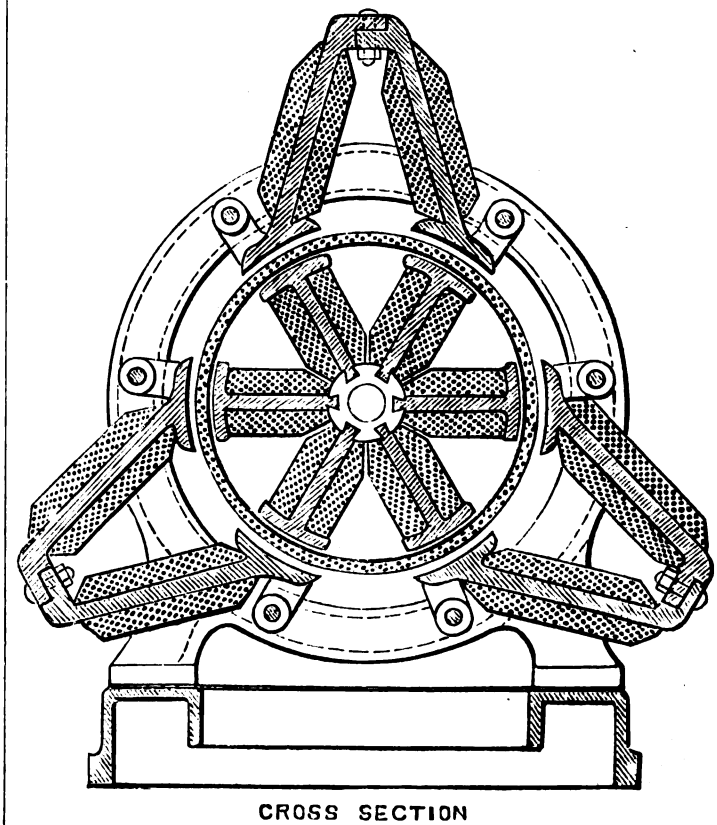

Fig. 1.—The Elphinstone-Vincent Dynamo Machine.

and (Fig. 2) a longitudinal section. A cylindrical drum armature rotates between exterior and interior magnets. The disposition of the twelve poles will be seen from the illustrations. This drum is of papier-maché, upon which the armature coils are laid longitudinally and retained by a wire winding. Each armature coil is made somewhat in the shape of the frame of a saddle. It consists of eighteen sections wound with double wire forming 36 coils. The resistance of the armature between the brushes is ·0374 ohm. There are six brushes. It is claimed that in these machines the openings in the coils cut most perfectly the powerful fields of force produced between the faces of the field magnets, and as

Digitized by Google

there is no iron in the armature, the speed with which it may profitably be made to revolve is only limited by its strength. At present the highest speed run is about 1,000 revolutions per minute, but modifications are being introduced which it is hoped will allow the speed to be increased to 1,500 revolutions per minute. At a speed of 855 revolutions per minute, the machine just finished, weighing 26 cwt., generated current sufficient for 288 Swan lamps. The E.M.F. at the brushes varies between 68·85 and 90 volts, depending on speed and external resistance. The resistance of a single outside arm of the field magnets is 1·93 ohm.

The following results of experiments have been handed to us. In these experiments the speed was taken from the countershaft from which the machine was being driven, so that a little allowance must be made for the possible slipping of the belt. The resistance was acidulated water, with lead plates as electrodes. The arrangement was as shown in Fig. 3, where T T represents the terminals of the machine, VM an Ayrton's voltmeter, and G a galvanometer for large currents. As we have said, the armature resistance = ·0374 ohm, while that of the field magnets is 17 ohms, or 4·25 ohms, according as they are used in series or in two parallels —terminals being provided for either method of connection. When the field magnets are joined up so as to have a resistance of 4·25 ohms, the maximum electric efficiency is said to be ·829; while, when the field magnets have a resistance of 17 ohms, the maximum electric efficiency is ·91 :—

The designers of this machine claim for it a number of advantages, such for example as the small amount of waste wire in the coils. Readers who have studied the recent Cantor lectures will know that in the Gramme machine there is a large quantity of useless wire, and that efforts have been made by various makers to minimise this waste. Machines having very different E.M.F.'s can be built upon the same framework. The coils are removable, and a faulty coil can be replaced in a short time. The separate circuits enable the inventor to have an armature with a low resistance, although comparatively thin wire is used. There is no magnetisation or demagnetisation of any part, and the inventors maintain that this is the most efficient system upon which to construct dynamo machines. As has been seen an efficiency of 82·9 to 91·0 per cent. can be obtained according to whether it is desired to attain the best return per h.-p. used, or maximum current without considering h.p. The amount of friction in the machine is small. The amount of current used to excite the field magnets may be varied while working, so that the efficiency of the machine is no question of speculation, but is absolutely de-

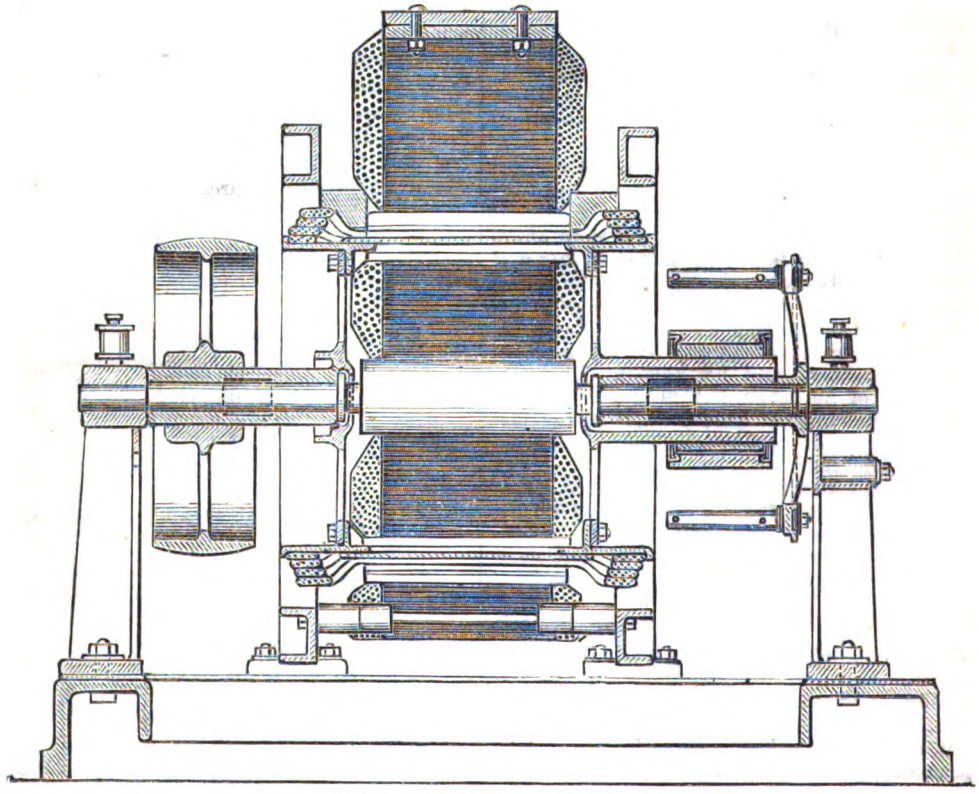

Fig. 2.—The Elphinstone-Vincent Dynamo Machine.

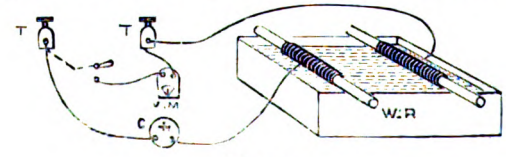

Fig. 3.

Digitized by Google

monstrable. The inventors express their opinion very strongly that such a degree of efficiency as 90 per cent. is absolutely unattainable in any machine in which the armature becomes even moderately hot. With 190 to 200 amperes of current the armature is barely perceptibly warmed. A question of mechanical construction has prevented those machines of which the tests are here given being driven at the desired speed of 1,100 or 1,200, which will be attained with some now constructing. The machines can be built of a size to light *a whole town* from a single machine, since its parts are capable of almost indefinite multiplication. We understand that one of these machines is in constant use in one of the recent Swan installations, and that the results of its working are very satisfactory.

Since the above was written we have received the following account of some experiments which were carried out on Monday last at Messrs. Unwin's printing works:—

The experiments were made with a machine running at erratic speed, and show the possibility of keeping a constant electromotive force under those conditions. The engine was driving the whole of the printing machinery at Messrs. Unwin's, as well as the dynamo machine. The time was 9 to 11 a.m. on Monday morning, steam low, and at the close of the experiments water was pumping into the boiler. Weston arc lamps—two in series—were on branches from the main circuit, the current through these was not taken into account; being nominally 30 volt lamps they burnt exceedingly well with 31·5 volts, *i.e.*, 63 volts through the series of two. The lamps were switched in and out at pleasure. The experiments were brought to an end when no current was left in the main circuit with which to steady the E.M.F. The speed of the machine was from barely 500 to 1,000 revolutions per minute. In the latter case the machine was doing no external work. Before any current was taken off the main circuit the readings were:—

MAIN CIRCUIT.

Amperes.	Volts between Terminals.
0	120
135	90
189	72
171	84
157·5	72
162	78
198	66

When the E.M.F. was kept steady and the branches opened the result was:—

MAIN CIRCUIT.

Amperes.	Volts.
135	63
135	61·5
112·5	63
117	63
63	61·5
0	63

Working incandescent lamps with fine filaments under these conditions would be a somewhat hazardous proceeding, but lamps of the coarse sort would work fairly well in parallel with arc lamps. It need hardly be said that no such trying ordeal is in store for the 300 to 400 Swan lamps, with which it is proposed to light Messrs. Unwin's premises. In actual working the speed of the machine will be kept tolerably uniform.

SOCIETY OF ARTS.—The following papers are set down for reading at the meetings of the Society of Arts during the part of the Session after Christmas:—Sir Frederick Bramwell, F.R.S., "Some Points in the Practice of the American Patent Office." Professor George Forbes, "The Electrical Transmission of Power." James J. Dobbie, D.Sc., and John Hutchinson, "On the Application of Electrolysis to Bleaching and Printing."

CANTOR LECTURES.*

DYNAMO-ELECTRIC MACHINERY.

BY PROFESSOR SILVANUS P. THOMPSON, B.A., D.SC., M.S.T.E.

Lecture II.—The Dynamo in Practice.

(CONTINUED FROM PAGE 212.)

It was pointed out, at the conclusion of the former lecture, that none of the four fundamental methods of exciting the field magnetism of a dynamo was perfect in theory, since none could enable a machine either to generate a constant current, or to maintain a constant electromotive force, whatever the resistance of the external circuit for the time being. Now, as the first function of a dynamo in practice is to feed with sufficiency and regularity a system of lamps, and, as those lamps are always† in practice arranged either in series or in parallel, it is clear that in the former case a constant current, and in the latter a constant electromotive force, is required.

Combination Methods.

The discovery of the method of rendering a dynamo machine automatically self-adjusting, so that either its electromotive force (according to circumstances) shall be constant, is due to M. Marcel Deprez, and is a result of the considerations arising from the study of the diagrams of the characteristic curves of dynamos.‡ M. Deprez has, in fact, shown mathematically that if a dynamo be wound with a double set of coils, one of which can be traversed by an independent current, whilst the other set is traversed by the current of the machine itself, there can always be found a certain critical velocity of driving, for which, provided the field-magnets are far removed from their saturation point, the desired condition is fulfilled. Other combination methods have been suggested by Professor Perry and others; and, as the whole matter promises to be of utmost importance in the future practice of constructing dynamos, a summary of the principal methods may be worth tabulating.

(1.) *Series and Separate (for Constant E.M.F.), Deprez.*—This method, illustrated in Fig. 16, can be applied to any

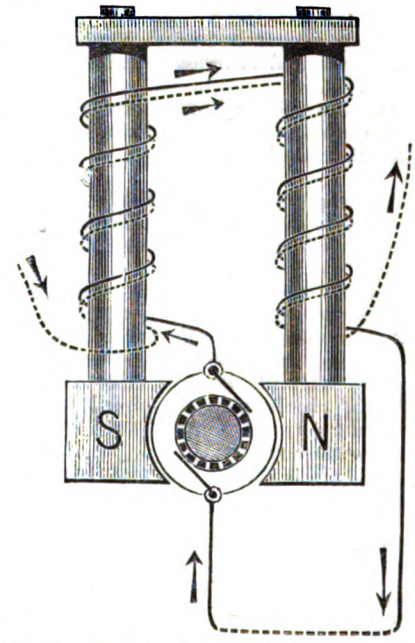

FIG. 16.—Combination of Series and Separate.

ordinary dynamo, provided the coils are such that a separate current from an independent source can be passed through a part of them, so that there shall be an initial magnetic field, independent of the main-circuit current of the dynamo. When the machine is running, the electromotive force producing the current will depend partly on this independent excitement, partly on the current's own excitement of the field-magnets. If the machine be run at such a speed that the quotient of the part of the electromotive force due to the self-excitement, divided by the strength of the current, is numerically equal to the internal resistance or the machinery, then the electromotive force in the circuit will be constant, however the external resistances are

* Reprinted from the *Journal of the Society of Arts*.

† I am aware that occasionally incandescent lamps have been arranged with two or three lamps, in series, in each parallel, or on a multiple series plan. I am not aware of any such arrangement having been satisfactory.

‡ See *La Lumière Electrique*, December 3, 1881.

Digitized by Google

varied. M. Deprez has further shown that this velocity can be deduced from experiment, and that, when the critical velocity has once been determined, the machine can be adjusted to work at any desired electromotive force, by varying the strength of the separately-exciting current to the desired degree.

(2.) *Shunt and Separate (for Constant Current), Deprez.*—When cases arise, as for a set of arc lamps in series, it is desired to maintain the current in the circuit at one constant strength, the previous arrangement must be modified, as indicated in Fig. 17,

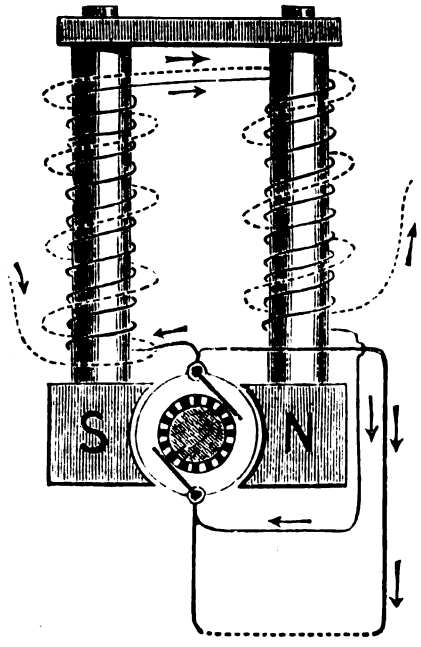

FIG. 17.—Shunt and Separate.

by combining a shunt-winding with coils for a separately-exciting current. This arrangement is, in fact, that of a shunt-dynamo, with an initial magnetic field independent of the strength of the current in the circuit.

Seeing that the only object in providing the coils for separate excitement is to secure an initial and independent magnetic field, it is clear that other means may be employed to bring about a similar result.

(3.) *Series and Magneto (Constant E.M.F.), Perry.*—The initial electromotive force in the circuit, required by Deprez's theory, need not necessarily consist in there being an initial magnetic field of independent origin. It is true that the addition of a permanent magnet, to give an initial partial magnetisation to the pole-pieces of the field magnets, would meet the case to a certain extent; but Professor Perry has adopted the more general solution of introducing into the circuit of a series-dynamo a separate magneto machine, also driven at a uniform speed, such that it produces in the circuit a constant electromotive force equal to that which it is desired should exist between the leading and return mains.*

* Professor Perry gives, in his specification, the following numerical illustration, to which the only exception that can be taken is, that with so high a resistance as that of three ohms in the machine the system must be very uneconomical. "As an example, if there is only one dynamo machine, and if the resistance of the main cable, return cable and machines, in fact, of that part of the total circuit which is supposed to be constant, be, let us suppose, three ohms, then we find that the dynamo machine ought to be run at such a speed that the electromotive force, in volts, produced in its moving parts is three times the current in amperes, which flows through the field-magnets, consequently this speed can readily be found by experiment. Suppose the constant electromotive force of the magneto machine to be 50 volts; its resistance 0·3 ohm, and the resistance of the dynamo machine and of the other unchanging parts of the circuit 2·7 ohms; and suppose that the speed is that at which the electromotive force produced by the rotating armature of the dynamo is three times the current. Now, let there be a consumer's resistance of 2 ohms, the total resistance is 5 ohms. Evidently the electromotive force produced in the dynamo is 75 volts (for call this electromotive force x, then the current will be $x \div 3$, whence it follows that $\frac{x + 50}{5} = \frac{x}{3}$, or $3x + 150 = 5x$, or $x = 75$), and the total electromotive force in the circuit is therefore 125 volts, and, as the total resistance is 5 ohms, the current is 25 amperes, giving an electromotive force of 50 volts between the ends of the consumers' part of the circuit. Now, if the consumers' resistance increases to, say, 12 ohms, by some of the consumers ceasing to use their circuits, there is an instantaneous alteration of the electromotive force produced in the dynamo to 12½ volts, or 62½ volts in the whole circuit, and 62½ divided by 15 gives 4 1-6 amperes; and this means 4 1-6 multiplied by 12 or 50 volts as before, between the ends of the consumers' part of the circuit. (Here, again, the calculation is:— $\frac{x + 50}{15} = \frac{x}{3}$, whence $x + 150 = x$, or $12\frac{1}{2} = x$.)—(S.P.T.)

This arrangement, which is depicted in Fig. 18, may be varied by using a shunt-wound dynamo, the magnets being, as before, included in the part of the circuit outside the machines. The combination of a permanent magnet with electro-magnets in one and the same machine is much older than the suggestions of either Deprez or Perry, having been described by Hjörth in 1854.

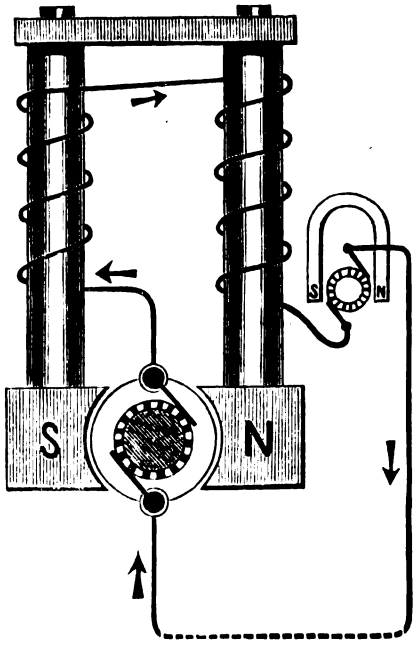

FIG. 18.—Series and Magneto.

(4.) *Shunt and Magneto (Constant Current), Perry.*—Perry's arrangement for constant current is given in diagram in Fig. 19, and consists in combining a shunt-dynamo with a magneto machine of independent electromotive force, this magneto-machine being inserted either in the armature part or in the magneto-shunt coils of the machine. As before, a certain critical speed must be found from experiment and calculation.

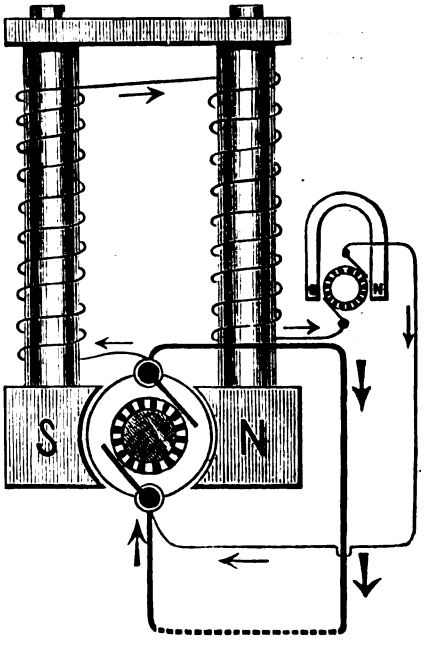

FIG. 19.—Shunt and Magneto.

(5.) *Series and Shunt.*—A dynamo having its coils wound, as in Fig. 20, so that the field-magnets are excited partly by the main current, partly by a current shunted across the brushes of the machine, is no novelty, having been used in Brush dynamos* for some years past. The arrangement is not so per-

* The shunt part of the circuit, originally called the "teazer," was adopted at first in machines for electro-plating, with the view of preventing a reversal of the current by an inversion of the magnetisation of the field-magnets, but has been retained in some other patterns of machine on account of its usefulness in "steadying" the current. I am informed that Messrs. Siemens and Halske have also used this combination for some time past.

Digitized by Google

fect as either of the preceding, being more limited in operation. If the shunt coils be comparatively few, and of high resistance, so that their magnetising power is small, the machine will give approximately a uniform electromotive force; whereas, if the shunt be relatively a powerful magnetiser, as compared with the

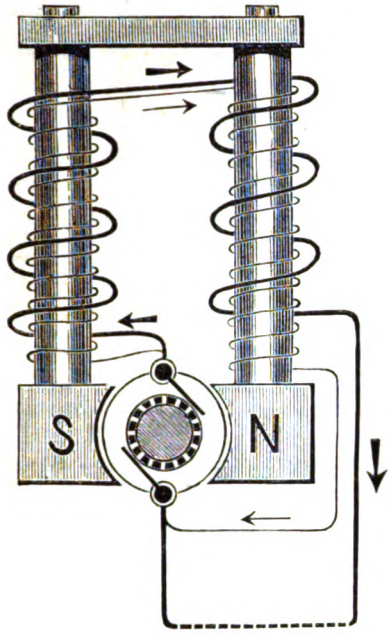

FIG. 20.—Series and Shunt.

few coils of the main circuit, the machine will be better adapted for giving a constant current; but, as before, each case will correspond to a certain critical speed depending on the arrangement of the machine.

(6.) *Series and Long Shunt.*—I propose to give this name to a combination closely resembling the preceding, which has not yet, so far as I am aware, been actually tried. If, as in Fig. 21, the

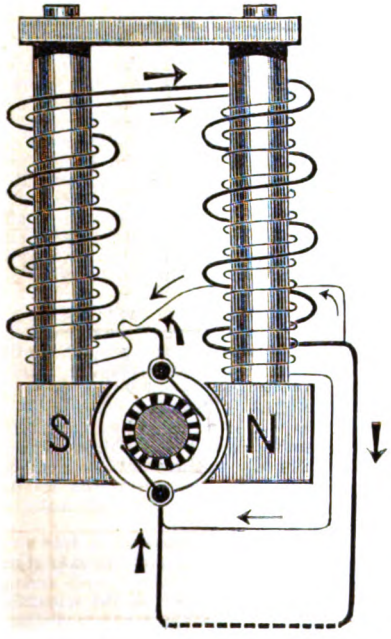

FIG. 21.—Series and Long-Shunt.

magnets are excited partly in series, but also partly by coils of finer wire, connected as a shunt *across the whole external circuit*, then the combination should be more applicable than the preceding to the case of a constant electromotive force, since any variation in the resistance of the external circuit will produce a greater effect in the "long shunt" than would be produced if the resistance of the field-magnets were included in the part of the main circuit external to the shunt.

Although the last two combinations are not such perfect solutions of the problem as those which precede, they are more likely, in my opinion, to find an immediate application,* since they can be put into practice upon any ordinary machine, and do not require, as in the first four combinations, the use of separate exciters, or of independent magneto-machines.

All these arrangements presuppose a constant velocity of driving; but they are not the only ones consistent with this condition. An ordinary series dynamo may be made to yield a constant current, by introducing across the field-magnets a shunt of variable resistance, the resistance of the shunt being adjusted automatically by an electro-magnet, whose coils form part of the circuit. This is actually done in the automatic regulator attached to Brush dynamos, as used in supplying a series of arc lights. A shunt-dynamo may similarly be controlled, so as to yield a uniform electromotive force, by introducing a variable resistance into the shunt-magnet circuit, as is done in some of Edison's dynamos. To make the arrangement perfect, this variable resistance should be automatically adjusted by an electro-magnet whose coils are an independent shunt across the mains of the external circuit.

Yet another way of accomplishing the regulation of dynamos is possible in practice, and this without the condition of a constant speed of driving. Let the ordinary centrifugal governor of the steam-engine be abandoned, and let the supply of steam be regulated, not by the condition of the velocity of driving, but by means of an electric governor, such as an electro-magnet working against an opposing spring. If this electro-magnetic governor is to maintain a constant electromotive force, its coils must be a shunt to the mains of the circuit. If it is to maintain a constant current, its coils must be part of the main circuit. Such a governor ought to be more reliable and rapid than any centrifugal governor intended to secure a uniform speed of driving.

Organs of Dynamos.

I now propose to return to some of the rules and suggestions which we arrived at a week ago, in considering the dynamo in theory, and see how they are borne out in the dynamo as constructed in practice. I shall try to illustrate the various points that come under review, as far as possible, from the more recent types of dynamo.

Field-Magnets.

In the classification of dynamos, laid down in my first lecture, we found that those of the first class required a single approximately uniform field of force, whilst those of the second class required a complex field of force differing in intensity and sign at different parts. Accordingly, we find a corresponding general demarcation between the field magnets in the two classes of machine. In the first, we have usually two pole pieces on opposite sides of a rotating armature. In the second, a couple of series of poles set alternately round a circumference or crown, the coils which rotate being set upon a frame between two such crowns of poles.

Confining ourselves, at first, to the first class of machines, we find that, in practice, their magnets differ widely in construction and design. In very few of the existing patterns is there much trouble taken to secure steady magnets, by making them long, heavy, and solid, or with very heavy pole pieces. I have repeatedly, in testing dynamos, had to report that an unnecessary amount of wire had been wound upon the field magnets; and I find that the usual reply is that, with less wire, the machine does not work so well. If, however, it is found necessary to wind on so many coils upon the magnets as to bring these practically to saturation long before the machine is doing its maximum work, it is clear that either the iron is insufficient in quantity, or it is deficient in quality. In the Bürgin machines, where cast-iron field magnets are employed, the smaller magnetic susceptibility of this metal is made up for by employing a great weight of it. In Siemens's smaller dynamos, the amount of iron employed in the field magnets would be quite insufficient if it were not of high quality. As it is, I am of opinion, the mass of it (especially in the polar parts) might, with advantage, be increased. In some of the early machines of Wilde, and in Edison's well-known dynamos, long field magnets, with heavy pole pieces, are found. Edison's dynamos, indeed, are all remarkable in this feature; the pole pieces and the yoke connecting the iron cores of the coils are made abnormally heavy. This is not more noticeable in the giant dynamos, used at the Holborn-viaduct, than in the smaller machines used in isolated installations for sixty and for fifteen lights.

The principle of shaping the magnets, so that their external form approximates to that of the magnetic curves of the lines

* Since the above was written, an account of a similar combination to the 5th, mentioned above, has appeared in the pages of *The Electrician*, under the name of "Crompton's Compound Dynamo." Mr. R. M. Bosanquet, of St. John's College, Oxford, has also suggested a similar arrangement for charging accumulators with a constant electromotive force.

Digitized by Google

of force, is, to some extent, carried out in such widely differing types of machine as the Gramme with "Jamin" magnet, the Jürgensen dynamo, and Thomson's "mousemill" dynamo. The two machines last named exhibit several curious contrasts. In the Jürgensen, the field-magnets have heavy poles pieces; in the Thomson there are none; and in the Thomson machine the iron core is thicker at the middle than at the ends. In both there are auxiliary internal electro-magnets, fixed within the rotating armature, to concentrate and augment the intensity of the field, according to the device patented by Lord Elphinstone and Mr. Vincent. In the Thomson machine the coils are heaped on more thickly at the middle of the field-magnets; in the Jürgensen, the coils are crowded up around the poles. The latter arrangement I condemned from the point of view of theory last week. If we may judge from a report on this machine by Professors Ayrton and Perry,* the arrangement is not satisfactory in practice, as there are more coils than suffice to magnetise the magnets. Is it possible that the mistake is not in having too many coils, but in having them in the wrong place?

Another suggestion, which was indicated from theoretical considerations, was that of laminating the pole-pieces, so as to prevent the production in them of wasteful Foucault currents. Here I find that but one machine has been designed in which this precaution is carried into effect. This is the disc-dynamo of Drs. Hopkinson and Muirhead, the field magnets of which are made up of laminæ of iron, cast into a solid iron backing.

Another matter in which, up to the present time at least, there is nothing but empirical practice to guide us, is the form to be given to pole pieces, in order to produce the best effect. In fact, we have such singular divergence in practice, as to suggest the thought that little importance has been attached to the matter. Yet upon the form and extent given to the pole pieces, depend considerations of no less importance than the reduction of idle wire in the armature, the reduction of sparking at the commutator, and the avoidance of counter-electromotive forces in the armature. If the pole pieces are badly shaped for their work, or approach one another too far round the armature, they may completely perturb the approximate uniformity of the field, and may cause the central portion of the field to be of much weaker intensity than the two lateral regions between the edges of the pole pieces. When this is the case, the rotating coils are virtually moving in a double field, and it is even possible that, in consequence, the direction of the currents induced in the individual coils may be reversed four or six times as they make one rotation. In such a case the distribution of potential round the separate bars of the commutator will be abnormal, as we shall see later on.

(TO BE CONTINUED.)

* See *Telegraph Journal and Electrical Review*, Sept. 23, 1882

INTERNATIONAL ELECTRIC EXHIBITION, VIENNA, 1883.

GENERAL REGULATIONS.

We have received a copy of the regulations relating to this exhibition, which are as follow:—

ARTICLE 1.—By a decree of the Imperial Ministry of Commerce of the 8th of June, 1882, No. 17,202, permission was given to hold an International Electric Exhibition in Vienna, and the Rotunda, together with the remaining buildings erected for the Universal Exhibition of 1873 devoted for this purpose.

ARTICLE 2.—This Exhibition shall be opened on the 1st of August and shall be closed on the 31st of October, 1883.

ARTICLE 3.—To organise and carry through the International Electric Exhibition, a General Commission has been formed which has secured the necessary means by a guaranteed fund. This General Commission has formed from among its members several committees, a central committee, a finance committee, a technical committee, a committee of arrangements, and shall form further committees as needed. A managing committee has been appointed to carry out the resolutions passed by the General Commission and by the several committees, and to manage all matters relative to the Exhibition. All communications with the representatives of foreign countries and with the exhibitors or their representatives shall be carried on through the Managing Committee.

ARTICLE 4.—The exhibits to be admitted are divided, according to the principle which they embody, into the following classes:—Class I. Magneto-electric and dynamo-electric machines. Class II. Galvanic cells, batteries, accumulators, thermo-electric piles. Class III. Scientific apparatus, instruments for electrical measurements, electrostatic apparatus. Class IV. Telegraphs. Class V. Telephones, microphones, photophones. Class VI. Electric lighting. Class VII. Transmission of power. Class VIII. Cables, wires, conductors. Class IX. Application of electricity to chemistry and metallurgy. Class X. Application of electricity to war. Class XI. Railroad electrical appliances. Class XII. Application of electricity to mining, navigation, and agriculture. Class XIII. Electro-medical apparatus. Class XIV. Application of electricity to automatic registration, to horology, meteorology, astronomy, and geodesy. Class XV. Miscellaneous. Class XVI. Application of electricity to domestic use, to art-industry and decoration. Class XVII. Application of machinery to electrical industry. Boilers, steam, gas and hydraulic engines. Class XVIII. Historical collections. Methods of instruction. Bibliography.

ARTICLE 5.—Applications for space so far as possible should be made out according to the annexed forms and must be in the hands of the managing committee of the International Electrical Exhibition, Wallfischgasse 9, Vienna, at the latest by the 1st March, 1383. Printed forms are to be obtained at home from the managing committee, the Boards of Trade and Commerce, from the scientific and commercial societies, and abroad from the Austrian-Hungarian Consuls. When necessary special local committees shall be formed to co-operate with the managing committee.

ARTICLE 6.—The acceptance of exhibits rests with the General Commission, applicants shall be informed of the decision of the commission within two weeks after receipt of application.

ARTICLE 7.—Exhibitors shall be informed of the final allotments of space by the 1st May of 1883.

ARTICLE 8.—Exhibitors shall pay no rent for the space allotted to them. The General Commission undertakes, at its own expense, the arrangement and general decoration of the building. Exhibitors must bear the expense of the installation and decoration of their own exhibits. The plans of these must be submitted to and approved of by the Managing Committee.

ARTICLE 9.—Motive power shall be supplied to exhibitors who require it at 20 kreuzers per h.-p. per hour (5d. or 10 cents). The motive power required for the purposes of the scientific commission shall be supplied free.

ARTICLE 10.—The Exhibition shall be open to the public twice daily, during the day and in the evening. The hours of admission shall be fixed and published in due course.

ARTICLE 11.—Exhibitors shall be entitled to free passes for themselves, their representatives, and for the requisite number of assistants and workmen.

ARTICLE 12.—The general commission shall provide that rigorous watch be kept over the exhibits and that proper order be maintained. The commission, however, does not hold itself responsible for any loss incurred through injury to exhibits through theft or fire. The exhibitors are at liberty to insure their exhibits at their own expense.

ARTICLE 13.—Exhibitors must provide that in the installation and working of their exhibits every danger to the public and to the buildings be avoided, and must conform themselves in this respect to special arrangements of the General Commission.

ARTICLE 14.—The exhibits must be accessible to the free inspection of the public every day during the regular hours of admission during the entire time of the exhibition. No exhibit shall be withdrawn before the close of the exhibition without the special permission of the General Commission.

ARTICLE 15.—Exhibitors must bear the expense of maintaining in order their own exhibits.

ARTICLE 16.—Exhibits must be in the name of the manufacturer, and with his consent they may also bear the name of the firm which is authorised to sell them. Every exhibit must be clearly marked with the name of the firm exhibiting.

ARTICLE 17.—All copies of exhibits, whether drawings, photographs, or otherwise, are only allowed with the consent of the exhibitors and of the General Commission.

ARTICLE 18.—The sale and removal of exhibits may occur with the consent of the General Commission; every object, however, withdrawn must be at once replaced by a duplicate.

ARTICLE 19.—The receipt of goods at the Rotunda shall begin on the 1st June, 1883, and by the 5th July, 1883, all exhibits must be entirely unpacked and set up. The General Commission reserves the right to dispose of the space not occupied by the specified date. The General Commission shall have the right to complete such installations as are not finished in time at the expense of the exhibitor, or to exclude him entirely.

ARTICLE 20.—One month after the close of the exhibition the exhibitors must have completely removed their exhibits. After the lapse of this time all exhibits not removed from the exhibition grounds shall be removed and deposited in some suitable place at the expense and risk of the exhibitor. In case of such goods not being removed within six months after the close of the Exhibition, they shall be sold and the proceeds made use of in accordance with Article 27.

ARTICLE 21.—The General Commission has taken the necessary steps to enable exhibitors to enjoy the advantage of the patent laws from the time of the entry of their goods to the exhibition grounds until exit therefrom, and to enable foreign exhibitors to enjoy exemption from duty in case of the re-export of their goods before the end of the year 1883. The special conditions relative hereto shall be given in due course.

ARTICLE 22.—No prizes will be awarded by a jury. During the exhibition, a technical and scientific commission shall be organised in co-operation with the exhibitors, in order to carry out electrical measurements and other scientific investigations with a view to testify results.

ARTICLE 23.—The General Commission shall make arrangements for scientific and technical lectures.

ARTICLE 24.—A complete catalogue shall be drawn up by the General Commission and published at the opening of the exhibition.

ARTICLE 25.—Further special regulations and arrangements relative to service, to the use of motive power, to the scientific experiments, to transportation of goods, to advertisements and to similar matters shall be duly sent to exhibitors, who shall also be kept informed of all important measures and occurrences.

ARTICLE 26.—The ultimate decision where cases of dispute or complaint may arise shall be reserved to the General Commission.

ARTICLE 27.—The net proceeds of the exhibition shall be devoted with the agreement of the Imperial Ministry of Commerce either to such scientific institutions as may carry out further the aims of the exhibition, or to the pursuit of important inventions in the field of electrical science.

Vienna, the 6th December, 1882.

For the General Commission of the Exhibition:

Honorary President: Graf Hans Wilczek. President: Victor Freiherr von Erlanger.

Managing Committee: Carl Pfaff. Rudolf Ritter von Grimburg.

EASTERN TELEGRAPH COMPANY.

Report and accounts of the directors for the half year ended 30th September, 1882, to be presented to the twenty-first half-yearly ordinary general meeting, to be held at the City Terminus Hotel, Cannon-street, in the City of London, on the 25th of January, 1883, at one o'clock:—The directors submit the accounts and balance-sheet for the six months ended 30th September, 1882. The revenue for the period amounted to £341,151 13s. 1d., from which are deducted £69,809 11s. 1d. for the ordinary expenses, and £52,801 5s. 6d. for expenditure relating to repairs and the laying of new cables, &c., during the half year. After providing £5,496 6s. 3d. for income-tax, there remains a balance of £213,044 10s. 3d., to which is added £1,033 18s. 7d. brought from the preceding half year, making a total available balance of £214,078 8s. 10d. From this balance £22,682 19s. 2d. has been paid for interest on debentures, and £20,559 2s. 2d. for dividend to 30th September, 1882, on the preference shares, leaving a balance of £170,836 7s. 6d. The directors have paid two interim dividends on the ordinary shares for the quarters ending 30th June and 30th September, 1882, and a bonus of 1s. per share for the half year, amounting together to £114,000. The balance, £56,836 7s. 6d., is carried forward to the next account. The revenue includes £15,600 dividend for the half year upon the Company's shares in the Eastern and South African Telegraph Company, being at the rate of 8 per cent. per annum, and also £3,551 16s. dividend for the like period on the shares of the Black Sea Telegraph Company belonging to this Company. The various sections of the Company's cables are in working order. All the Company's land lines between Alexandria and Suez were cut at the commencement of hostilities in Egypt, and were not restored until the fall of Tel-el-Kebir. The total interruption of telegraphic communication through Egypt was of course productive of great inconvenience to the public and loss to the Company, but the latter was to some extent compensated by the extra business arising from the naval and military operations of Her Majesty's Government in that country. In order to facilitate these operations and to obtain a resumption of through traffic as early as possible, an arrangement was made by the directors with Her Majesty's Government and His Highness the Khedive, under which a cable was laid by the Company's s.s. John Pender between Alexandria and Port Said, and a temporary land line was erected between Port Said and Suez by way of the Canal. An agreement was subsequently entered into with the Suez Canal Company for the erection and working of a permanent aerial line connecting the cables at Port Said and Suez, and to be used by the Company as an alternative route through Egypt to Aden, India and beyond. This work is now being carried out. In continuation of the new route, and with the view of expediting the important traffic with the Cape of Good Hope and Natal, the directors have made a contract with the Telegraph Construction and Maintenance Company for the manufacture and laying of a third cable between Suez and Aden, which cannot fail to be of great advantage in the working of the increasing business over that section. The cost of this cable, and of that between Alexandria and Port Said, will amount to about £320,000, the greater part of which it is proposed to take from the reserve fund. The above operations, although involving a large expenditure, were, in the opinion of the directors, absolutely necessary alike in the interests of the Company and of the public. Her Majesty's Government have recognised the important services rendered by the Company in official correspondence which will favourably affect the future position of the Company. During the half year the Company's ships have been fully occupied. The s.s. Chiltern served as a floating station at Alexandria for three months, after which the s.s. John Pender performed that duty, the Chiltern being employed in the repairs of the Red Sea and Bombay cables. The s.s. Caroline was chartered for conveyance of cable and stores, and the Telegraph Construction and Maintenance Company's s.s. Seine was employed in the repairs of the Direct Lisbon cable, which she successfully accomplished on the 12th August in 2,700 fathoms of water, the Company's s.s. Retriever rendering assistance in the work. The directors have purchased and equipped a new repairing steamer, the Volta, of a similar class to the Retriever, experience having shown that repairing operations can frequently be carried out successfully and economically by vessels of this tonnage. The new vessel will be paid for out of the maintenance ships fund. The new cable (referred to in the last report) from Malta to Tripoli was opened for traffic on the 27th October, 1882. An agreement has been made with the Direct Spanish Telegraph Company which it is expected will be for the benefit of both companies, and tend to improve the working of the traffic. In accordance with the provisions of the Articles of Association, two of the directors—Lord Sackville A. Cecil and General Lord Alfred Paget—retire by rotation, and, being eligible, offer themselves for re-election. The auditors, Mr. Henry Dever and Messrs. Quilter, Ball, and Co., retire and offer themselves for re-election. A form of proxy is enclosed, which, to be available, should be signed and returned to the secretary on or before the 22nd inst.

THE ANGLO-AMERICAN BRUSH ELECTRIC LIGHT CORPORATION.

The report of this Company states that the capital has been increased to £245,000 by the issue of 700 fully paid up shares as compromise to American vendors in regard to mutual claims in connection with the Belgian and Russian patents. The value of all the patents of the Company is now stated at £179,466. The purchase of the Russian, Italian, and Scandinavian patents is not yet completed, and the Company have an interest of one-third in the future profits on account of the French patents. The balances of the year show a cash profit for concessions of £407,295, and on manufacturing account of £33,713, making a total of £443,943. Out of these balances an interim dividend of 100 per cent was paid, leaving £198,937, to which is to be added a further sum of £50,000 to be paid in March by Mr. Lane-Fox. The directors propose to deal with this sum by writing off from the purchase price of the patents £132,950, which will be represented in future by shares in the sub-companies; and write off also 10 per cent. on account of depreciation. The non-payment of dividend for the half year just closed is explained by the fact that the Company have stocks on hand, the cost price of which is £93,000, but the sale of which at large profits has been interrupted by the action of the Electric Lighting Act. The directors express, in conclusion, their regret that the extraordinary prosperity which attended their efforts during the early part of the past year has been followed by a temporary reaction towards its close, resulting from circumstances beyond their control. They cannot, however, but believe that when the numerous provisional orders now applied for, both by municipal authorities and by the licensees of the Corporation, have been obtained, a fresh impetus will be given to electric lighting generally. The secretary writes further that, at a recent Board meeting, it was found "that the total amount in cash and shares standing to the credit of the Corporation on the 31st of December last was £248,937 15s. 2d. From this amount they (the Board) propose, subject to the confirmation of the shareholders, to write off £132,950 in shares from the purchase price of patents, and £6,649 2s. 2d. for 10 per cent. depreciation of plant, buildings, &c., leaving £109,338 13s. to be carried forward to the credit of profit and loss account for 1883. The directors consider, having regard to the large stocks on hand, and the present temporary depression of electric lighting business, that they will be adopting the more prudent course in abstaining from declaring any dividend for 1882 further than the 100 per cent. already paid in that year."

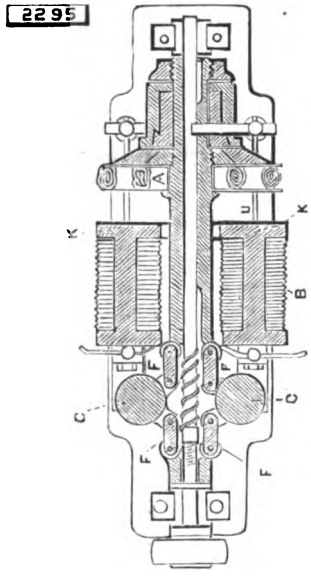
RECENT INVENTIONS.

ABSTRACT OF SPECIFICATIONS.

2295. IMPROVEMENTS IN COMPENSATING DYNAMO-ELECTRIC MACHINES, *B. H. Chameroy, Maisons Lafitte, France.*—16*th May*, 1882. 6*d*.

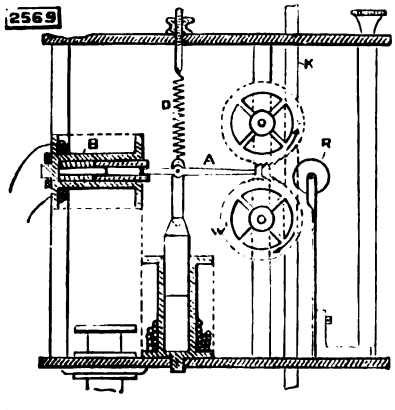
The inventor claims a dynamo-electric machine in which the strength of the current is controlled by causing the variations of said current to regulate the distance between the exciting coils and the electro-magnets, either directly by the influence of the current in the machine, or by the intervention of mechanical devices. The figure



gives a sectional plan of one method. The electro-magnets are movable, and supported on axles C C; they are capable of moving away from armature A. If any lamps connected with the dynamo are extinguished so as to increase its resistance, the lower part of electro-magnets K K will, by reason of their magnetisation, move towards the metallic masses F F1, and the separation of K K from A diminishes the current in A.

2569. IMPROVEMENTS IN ELECTRIC LAMPS, *T. E. Gatehouse, Camberwell, and H. R. Kempe, Barnet.*—31*st May*, 1882. 6*d*.

The accompanying figure shows the inventor's lamp. The solenoid B is connected through any make or break arrangement, so that it is intermittently excited, attracting its core in opposition



to the spring shown in the figure, and thus giving a reciprocating to-and-fro motion to arm A. Lower solenoid is of high resistance, and is placed in a shunt from the main circuit. Its core is drawn upward by an adjustable spring, D. When the carbons are too near this solenoid is weak, and spring D raises arm A, so that a tooth at its end engages as a pawl with the upper wheel. By the reciprocation of arm A this wheel is caused to turn upwards the same way as the arrow, thus raising the carbon and enlarging the arc. The reverse takes place when the arc is too long and the solenoid strong. Wheel R simply presses carbon K against wheels W and W1. The invention also relates to a novel method of including an incandescent lamp in a shunt circuit as part of the resistance thereof.

2532. AN IMPROVED METHOD OF TREATING CERTAIN MATERIALS TO RENDER THEM DIELECTRICAL, *E. W. Beckingsale, Bedford Park, Middlesex.*—27*th May*, 1882.—(*Not proceeded with.*) 2*d*.

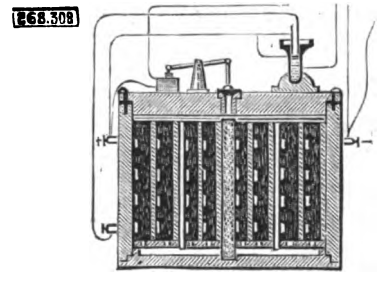
This relates to the injection of hydrocarbons into bricks, stones, and other porous materials, so as to render them non-conducting.

2628. IMPROVEMENTS IN APPARATUS FOR COLLECTING AND TRANSMITTING ELECTRIC FLUID, *&c., H. Defty, Middlesbrough.*—5*th June*, 1882.—(*Not proceeded with.*) 2*d*.

This invention relates to apparatus for collecting electricity from the natural chemical combinations of metals and ores, and transmitting the same for illuminating and other purposes.

268,308. SECONDARY BATTERY, *Eli T. Starr and E. Eugene Starr, Philadelphia, Pa.*—*Filed October 6th*, 1882.

Claim.—(1) The combination, substantially as hereinbefore set forth, of a closed battery vessel containing electrodes or elements, a valve closing an opening in said vessel, an electro-magnet to control said valve, and an electric circuit, substantially as described, including said electrodes and said magnet, whereby during the time the battery is giving off gas the said valve will be automatically opened to permit of its escape and at other times will be closed. (2) The combination, substantially as hereinbefore set forth, of an air-tight secondary battery vessel, electrodes contained in said vessel, a valve closing an opening in the said vessel, an electro-magnet mounted on said vessel to control said valve, and a line in which said electro-magnet is situated, by which the charging current is conducted to said battery, whereby while the charging current is passing to the battery the valve will be raised to permit the escape of surplus gases generated in the battery by said current, and when the charging current is cut off said valve will be closed. (3) An element or electrode for secondary batteries, consisting of a support or plate with a layer of porous active material applied thereto, composed of oxide of lead or its equivalent, mixed with fibre or



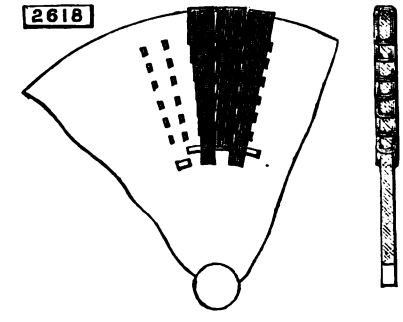
filaments—in contradistinction to pulverised coke or sawdust—whereby the porous mass is bound together and held more securely to its support or plate. (4) The improved porous active composition for secondary batteries, consisting of a mixture of lead or its quivalent with fibre or filaments, substantially as described. (5) The combination, substantially as hereinbefore set forth, in a secondary battery, of the battery vessel, the positive and negative electrodes thereof, each electrode consisting of a series of plates coated with porous material to be acted upon by the charging current, and each electrode being provided with a space extending through it for the free escape of the surplus gases, and the porous partition separating said electrodes. (6) The combination, substantially as hereinbefore set forth, in a secondary battery, of the closed battery vessel having a valve opening at its top for the escape of its surplus gases generated in charging the battery, the perforated partition forming a space at the bottom of the battery, the electrodes of said battery supported by said partition, and terminating below the top of the battery vessel to form a space thereat, and tubes or openings affording free communication between said spaces at the top and bottom of the battery. (7) The combination, substantially, as hereinbefore set forth, in a secondary battery, of the battery vessel, the electrodes of the battery terminating at top, so as to leave a space for the collection of the surplus gases generated in the battery, and vertical tubes or spaces extending through the electrodes to facilitate the collection of the gases in the space at the top of the battery.

2619. IMPROVEMENTS IN APPARATUS CONNECTED WITH ELECTRIC LIGHTING, *R. E. B. Crompton, London.*—3*rd June*, 1882.—(*Not proceeded with.*) 2*d*.

This relates to arc lamps, and to the regulation of both carbons by means of pulleys and cords, &c.

2618. IMPROVEMENTS IN DYNAMO-ELECTRIC MACHINES, *R. E. B. Crompton, London.*—3*rd June*, 1882. 6*d*.

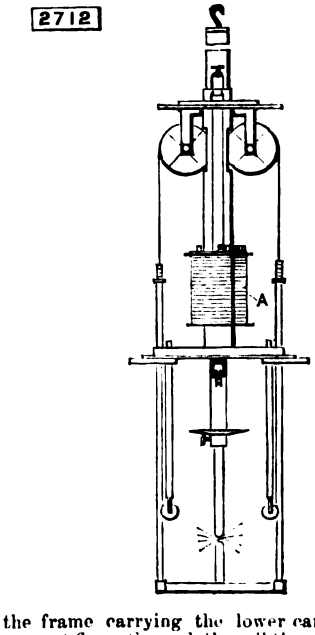
This relates to an improved method of winding disc armatures. The inventor divides the disc into as many segments as there are intended to be separate coils, and on each segment he winds as many equal and parallel turns of wire as its inner circumferential width will admit of; he



then continues the winding through a series of holes pierced through the disc, or steps cut in the segments, in such manner that each successive turn is shorter than the one preceding it. In this manner he fills up the otherwise unoccupied triangles with winding in a series of turns arranged stepwise, as shown in the accompanying figures.

2712. IMPROVEMENTS IN ELECTRIC LAMPS, *W. R. Lake, London, 9th June*, 1882.—((*A communication from F. Krizik and L. Piette, Pilsen, Austria*). 6*d*.

This relates to an improved means of regulating the arc. The upper carbon is attached to an iron core, thick at the bottom, but tapering to a point at its top, which works in and is the core of electro magnet A. This core is also connected by the pulleys and cords, shown in the figure, to



the frame carrying the lower carbon. When a current flows through the coil the core is attracted upward and the arc struck, and the balance between the attractive force of the coil and the weight of the frame carrying the lower carbon equalised. As the arc increases the current weakens, and the weight of the iron core overcomes the attraction of the coil sufficiently to let the carbons approach so as to again equalise the balance.

2674. IMPROVEMENTS IN ELECTRIC ARC LAMPS, *E. de Pass, London.*—7*th June*, 1882.—(*A communication from J. Gloker, Paris.*)—(*Not proceeded with.*) 2*d*.

This relates to an arc lamp, in which the upper carbon is regulated by means of two solenoids and an armature.

SLIP

POSTAL TELEGRAPHS.—Mr. J. Samuel, sorting clerk and telegraphist at Swansea, has been appointed Postmaster of Arundel.

LEWISHAM.—The Lewisham District Board of Works have retained Mr. Shoolbred, electrical engineer, to advise them in the matter of provisional orders.

BIRMINGHAM AND WARWICKSHIRE BRUSH ELECTRIC LIGHT COMPANY.—Mr. T. H. Seymour Hawker has been appointed electrician to this company.

SOUTH EASTERN RAILWAY TELEGRAPHS.—Mr. William Leonard has been appointed to succeed the late Mr. C. V. Walker as superintendent of telegraphs on this line.

AN EXHIBITION AT ZURICH.—A national exhibition is to be held at Zurich, in Switzerland, this year. Telegraphy, telephony, and other applications of electricity will be represented.

ELECTRIC LIGHTING AND SUGAR PLANTERS.—It is stated that some of the sugar planters in the Hawaiian Islands are now utilising electric lights to enable them to cut their cane at night.

CHANNEL ISLANDS.—The cable to Guernsey is interrupted. Telegrams for Jersey have, therefore, to be wired either by way of France, or forwarded by steamer to Guernsey, and thence by cable.

SIAMESE TELEGRAPHS.—News from Marseilles says that the "Irrawaddy" has left with eight French telegraphists for the King of Siam, who intends to establish a telegraphic station at Bankok.

WEST INDIA AND PANAMA TELEGRAPH COMPANY.—The estimated traffic receipts of this company for the half-month ended Jan. 15 were £2,118, as compared with £2,188 in the corresponding period of 1882.

CABLE REPAIRED.—The Eastern Telegraph Company notifies the restoration of the Porthcurnow-Vigo cable, which was interrupted last week, thus restoring this company's duplicate means of communication with the Peninsular.

GENEROSITY.—Dr. Stephan, the German Postmaster-General, has received a remittance of 200gs from the Indo-European Telegraph Company, as a subscription to the fund now being raised on behalf of the victims of the late inundations in the Rhine districts.

MESSRS. W. GLOVER AND CO.—We are informed that this well-known Manchester firm of wire manufacturers have opened offices at 28, Budge-row, Cannon-street, London, E.C., under the charge of Mr. A. L. Craig. Their telephone exchange number is 1,784.

THE WHEATSTONE SYSTEM IN FRANCE.—This system, which has recently found such favour in the eyes of American telegraphists, is now to be introduced on French lines. Operators are being sent from the provinces to Paris to learn how to manipulate the apparatus.

VIBERT V. EASTERN TELEGRAPH COMPANY.—This case, which was for wrongful dismissal, was tried at the New Law Courts on the 25th inst., with the result that a verdict for the defendant Company was found, on the ground that plaintiff had received sufficient notice.

ELECTRIC EXHIBITION AT PHILADELPHIA.—The Engineers' Club, of Philadelphia (U.S.A.) have suggested the advisability of holding an exhibition of the progress and products of modern electric engineering. The matter has been referred to the Board of Directors.

THE TELEPHONE IN PARIS.—Besides its ordinary working lines, the Société Générale des Téléphones has established, since its formation in 1880, 200 private lines and more than 2,000 telephonic posts, in Paris and the provinces. M. Hospitalier is our authority for this statement.

POSTAL TELEGRAPH ENGINEERS.—The clerical staff and inspectors of the Divisional Engineer, Metropolitan District, held their annual dinner at the New Gresham, on Monday evening last. About forty persons were present, Mr. H. Eaton, the head of the branch, presiding.

"GREAT SUN SPOTS."—An interesting article on this subject appeared in *The Times* of Tuesday. The writer referred to the now little doubted connection between sun spots and the phenomena of terrestrial magnetism, first indicated by Sabine, and alluded to the disturbances of 1859.

ELECTRIC LIGHTING AT MONTREAL (CANADA).—Describing the opening of the Ice Carnival at Montreal, the correspondent of a daily paper describes the city as being "brilliant with electric lights" at night time. We can quite imagine that the arc lights would look at their best in the court of King Frost.

"L'ELECTRICITE."—Our Paris contemporary, *L'Electricité*, has taken a new lease of vitality with the new year, and now appears better printed, on better paper, and in better garb altogether. We congratulate our contemporary upon its present appearance, and hope that the new year may increase its prosperity.
